Of the 25 patients now under review almost all came to the hospital with lesions actually discharging or with an abscess ready to be evacuated. In such circumstances the diagnosis need never be long in doubt. All that is then required is to detect the "sulphur granules" in the pus and to determine their mycelial structure. A little experience of these granules enables one very readily to recognise them, either as the pus is evacuated or lying free on the granulations at the mouth of a sinus.

A word of warning may not be out of place here. Cases of actinomycosis are not infrequently missed, I think, because the surgeon does not himself search for granules in the fresh pus, but simply directs a specimen to be sent to the laboratory. Pending its examination the pus clots and the granules, being caught up in the coagulum, become more difficult to detect. Moreover, the pathologist, often not forewarned that the nature of the case suggests the possibility of actinomycotic infection, does not search for a granule, but takes a loopful of pus at random for film preparations and the inoculation of culture medium. Unless he has the good fortune (a somewhat rare occurrence) to include a commencing colony of actinomyces in such a random sample of pus he is very unlikely to find any filaments of that organism, for these, by reason of their habit of growth in conglomerate masses, do not become disseminated through the pus.

The following simple procedure may be recommended for the detection of granules whenever their presence is in doubt. A few drops of pus are collected in a test-tube half full of water and fitted with a cork. On *vigorously* shaking the tube all the elements of ordinary pus will be emulsified or at least reduced to fine shreds; if, however, actinomycotic granules are present they will not be broken up, and on holding the tube up to a light will be easily detected by virtue of their opacity as cream-coloured spherical bodies of about $\frac{1}{2}$ to 1 mm. diameter, which quickly sink to the bottom of the fluid.

With the finding of granules a provisional diagnosis of actinomycosis can be made. For confirmation of the diagnosis it remains to verify the presumption that these granules are composed of Gram-staining mycelial elements, and, whenever possible, to identify the organism by isolating it in pure culture. For these purposes the granules are transferred as required by means of a capillary pipette to the surface of a microscopic slide. Lightly crushed under a cover-glass and examined unstained with a low power objective, the characteristic "ray" formation of clubs will be seen between an outer shell of massed leucocytes and the inner core of the granule. The "rays" form, in fact, the whole periphery of this core. On crushing further and staining the films obtained by sliding the cover-slip off the slide the core itself is seen to be composed of a tangle of the filaments of actinomyces. These filaments retain Gram's stain, but somewhat irregularly. The further procedures necessary for obtaining cultures—and the characters by which a given organism may be identified with *Actinomyces bovis*—are described in the author's earlier paper.[1]

THE INCIDENCE OF THE DISEASE AND ITS ULTIMATE ISSUE.

There is reason to think that actinomycosis occurs more frequently in this country than is generally supposed. In the cases which end fatally a correct bacteriological diagnosis is often made only when the disease is far advanced, or post-mortem, and it therefore appears probable that a large number of the less severe cases escape recognition altogether—notably those cases in which the infection is situated about the lower jaw, and possibly also, as Mr. Slesinger[3] has suggested, some of those in which the vermiform appendix is affected. In Table I. the patients observed by the author are divided up according to the site of their infection; the incidence in the two sexes is also shown, and the ultimate issue of the disease.

TABLE I.

Site of infection.	No. of cases.	Males.	Females.	Ultimate result.
Face or neck ...	10	7	3	9 recovered completely; 1 died.*
Thorax	8	5	3	7 died; 1 lost sight of.
Abdomen... ...	6	1	5	5 died; 1 recovered.
Dorsum of hand	1	1	—	Recovered completely.
Total	25	14	11	—

* Death was due to cerebral abscess, resulting from direct extension of the disease through the skull.

Table I. confirms the usual experience that (*a*) cervico-facial infections are the most numerous and also the most likely to recover; (*b*) infections of the thorax and abdomen are usually fatal. The latter conclusion should perhaps be stated with some reserve, for the future may show that actinomycotic infections of the vermiform appendix occur much more commonly than has been supposed, and that many such cases are promptly cured by the ordinary operation of appendicectomy. (Slesinger.[4])

Age of the cases.—Seventeen of the 28 cases were young adults, 7 were older subjects (one of them being 70 years of age), and 4 were children between the ages of 10 and 13. I have not known the disease to occur below the age of 9.

Duration of the disease.—The course of these infections was commonly a very slow one. The disease had usually been in progress for several months before the patients came to the hospital for treatment, and although in three or four instances cure was obtained within a few weeks, the larger number of those who recovered were under treatment for a period of months. One case in whom the infection extended widely in the ramus of the mandible was apparently cured after three to four years, but a small focus reappeared in front of the ear and has persisted for a further two years. The fatal cases of thoracic or abdominal infection usually survived from one to two years from the onset of the disease. One abdominal case was terminated abruptly after several weeks in hospital by the development of septic peritonitis.

THE TISSUES AFFECTED BY THE DISEASE.

The outstanding feature of the pathological process in all the cases has been the extension by direct erosion of contiguous tissues—particularly connective tissues. Such extension has usually been accompanied by a deep induration, often quite a "wooden" induration over a considerable area around. Although the opportunity has not occurred to prove it by microscopical examination, one may, I think, surmise that this induration extends far beyond the area actually invaded by the actinomyces, for frequently, when a central abscess cavity has been evacuated, the indurated tissues promptly regained their normal softness. (It may be noted here, in passing, that no one has, so far as I am aware, succeeded in reproducing an actinomycotic lesion which has these two characteristics—progressive erosion of connective tissues and "wooden" induration—in any of the ordinary laboratory animals.)

The process of erosion has not involved the skin except in the immediate neighbourhood of sinus openings. In some cases, however, a considerable area of skin has been undermined by the spread of the disease in the subcutaneous connective tissue. The mucous membranes also seemed to be comparatively immune. It is a remarkable and, as yet, an unexplained fact that in the cervico-facial cases, although the infection presumably occurs from within the mouth or pharynx, the suppurative process almost always develops outwards towards the skin and seldom points in the mouth. None of the ten cervico-facial cases presented any evidence of the disease in the mouth when seen by the author, but three of them gave a history which pointed to its probable commencement in that situation. In one case the tonsil was incised at the first visit to the hospital, in another case a tooth was removed for an alveolar abscess, and in the third "incisions were made both inside and outside the mouth."

The involvement of bone, as judged by ante-mortem observations, has been exceptional rather than usual. Very possibly post-mortem examinations of the fatal thoracic and abdominal cases would have told a different tale. In one case (No. 6 of Mr. Cope's series[2]) the mandible was extensively tunnelled by little canals lined with granulation tissue, and much new bone formation—particularly of the outer lamella—had occurred. The periosteum was involved in a dense, fibrous, almost avascular tumour. This was the only case in which the changes in bone constituted a notable feature. In several other cases bones adjacent to an actinomycotic infection of the soft parts were eroded and sometimes perforated by it in the course of the disease, but in every instance this involvement was apparently limited to a small area. The ribs and sternum, the ileum and the temporal bone were affected in this way.

The remarkable immunity of the lymphatic glands in this disease, which has frequently been noted by other observers, was again evidenced in this series of cases. I do not remember having seen these glands affected in any case during life, and in one abdominal case which was examined post mortem, although the disease had spread widely, the mesenteric glands were quite unaffected.

TREATMENT.

Most of the cases had been treated by potassium iodide and by incisions before coming to the Inoculation Department at St. Mary's Hospital. The iodide had not usually been pushed beyond 30–40 gr. per diem; in one or two instances 60–90 gr. had been given. In these doses the drug had not exercised any appreciable effect upon the disease. Its use was usually discontinued soon after the patients came under observation; in a few instances, however, on the suggestion of the surgeon who was collaborating in the treatment of a patient, the drug was continued and pushed up to 180 gr. or more per diem, but still without effecting any improvement in the patient's condition. It should be acknowledged that the patients so treated were very unfavourable cases.

Upon inquiring into the origin and the general experience of this method of treatment I have failed to find that it has an assured scientific basis, or even a sufficient vindication by results. Introduced empirically by Thomassen[4] in 1885 for actinomycosis of the tongue in cattle, it was later acclaimed by Nocard[5] (1893) as an almost infallible remedy for this condition. When it came to be applied to the treatment of other actinomycotic lesions in cattle the results seem to have been less uniformly good, but I understand that it is still regarded by the veterinarians as a specific remedy.

Investigations undertaken with a view to finding an explanation of its reputed specific action have so far been quite unsuccessful. The organism does not lend itself readily to the demonstration of bactericidal effects, but observations have been made by Harbitz and Grondahl[6] on the growth obtained when potassium iodide was incorporated in various culture media. They concluded that *Actinomyces bovis* was but little affected by the presence of iodide in concentrations of from 0·25 to 2 per cent.

At St. Mary's Hospital we have approached the problem from a different point of view. It occurred to Captain S. R. Douglas that the resolution of syphilitic gummata under treatment with iodide might perhaps depend upon a reduction of the antitryptic power of the blood, and that a similar change might lead to the breaking down and cure of actinomycotic lesions. With this in view my former colleague, Dr. E. Beaton (1911*) made a number of estimations of the antitryptic power of patients' blood before and after administration of iodide. A slight reduction occurred when the drug was given in doses of from 30 to 60 gr. per diem. A much more striking effect on the antitryptic power was observed when iodine dissolved in potassium iodide was added to serum in vitro. One part in 1200 of iodine with 1 in 600 of potassium iodide reduced the antitryptic power by about 65 per cent. when the mixture was incubated for half an hour at 37° C. Half that concentration effected a 20 per cent. reduction. When the same drugs were mixed with trypsin solution in similar concentration its proteolytic power was curtailed to a much smaller degree.

Jobling and Petersen,[7] working with a similar conception in view, but using a different method for the estimation of the antitryptic power, obtained results which confirmed those of Beaton. The blood of patients to whom potassium iodide was being administered, in doses of 110 gr. per diem on the average, showed a very distinct reduction in antitryptic power. These authors consider the question whether, when iodides are administered to syphilitic and tuberculous patients, iodine is set free in any considerable quantity in the necrotic tissues; and they quote the experiments of O. Loeb,[8] which suggest that such is the case. Loeb found that unsoftened lymph glands of syphilitic patients contained 3·3 times, and softened glands 6·2 times as much iodine as the blood of the same patients. In conclusion, Jobling and Petersen express the view that "Iodin neutralises the action of the agents which prevent solution and absorption of necrotic tissue, and at the same time lays bare to the action of the real germicidal agent the infecting organism which previously had been protected by the necrotic tissue." If this view is upheld by further experimental work it might well apply also to the case of actinomycosis and would suggest that good results are to be expected from the administration of iodide in that disease only when necrotic foci require to be broken down. In other circumstances the action of the drug might conceivably be harmful, for *Actinomyces bovis*, like other serosaprophytic microbes, finds a congenial medium in serum whose antitryptic power has been reduced, whereas it is unable to grow in the unaltered serum. It may be noted in this connexion that many observers have reported harmful effects of the use of potassium iodide in tuberculosis.

---

* Unpublished researches.

When we turn to the actual results of treatment by potassium iodide we find very conflicting accounts. In 1898 Poncet and Berard[9] analysed the records of 105 cases—25 of them severe, 80 of them less severe and considered as favourable to the treatment. These authors recognise the difficulty of apportioning the credit due to the iodide when its administration is only an adjuvant to surgical measures, which manifestly exercise a great effect upon the disease. Their summing up was as follows: "Dans les deux tiers des cas d'actinomycose cervico-faciale ancienne, infectée et ouverte, le résultat du traitement ioduré a semblé nul. Dans les trois quarts des cas d'actinomycose récente, fermée et peu infectée, la guérison a été obtenue par l'adjonction de l'iodure au traitement chirurgical, dans un quart par le traitement ioduré seul. Ces derniers résultats ne sont pas sensiblément supérieurs a ceux que l'on a observés après le traitement chirurgical seul ou associé au traitement général. *L'iodure de potassium ne saurait donc être condidéré comme le médicament specifique de l'actinomycose.* ...... Dans les formes viscérales profondes, difficilement accessibles au chirurgien, l'iodure n'est susceptible d'entraver l'évolution du parasite que tout à fait a la période de début; mais, à cette période, souvent, le diagnostic reste très hésitant. Plus tard, les infections surajoutées, rendent illusoires l'emploi de l'iodure, qui n'agit rarement, à doses massives et prolongées, et encore faut-il, la plupart du temps, qu'une intervention chirurgicale palliative puisse lui venir en aide."

This judgment has been substantially borne out by later experience. It is now generally recognised that the administration of iodide, even in very large doses, has little or no effect upon the more severe infections; while the multiplication of other remedies—e.g., copper salts, methylene blue, X rays, salvarsan, radium, &c.—which have recently been advocated even for the milder infections, shows that the trend of opinion is increasingly unfavourable to the efficacy of the iodide treatment. I would suggest that the latter, if employed at all, should be limited to cases which present large unsoftened foci, and that it should be discontinued as soon as these have broken down.

Speaking generally, the treatment of the patients while under the author's care was (*a*) by surgical measures, and (*b*) by the inoculation of vaccines. The surgical measures taken were usually confined to incisions for the evacuation of pus and curetting. In connexion with each of these procedures something was learned from our experience. We learned, in the first place, that a single incision will seldom suffice to maintain satisfactory drainage of an actinomycotic focus. It is characteristic of this infection in man that it spreads by direct extension in contiguous tissues—particularly in the connective tissues—and leads to the formation of small abscess cavities here and there along the line of spread. To check the invasion one must be constantly on the watch for fresh areas of induration and softening, and must resort early to incision of these as often as they appear. My experience leads me to conclude that this policy of early and, if necessary, repeated incisions, is of paramount importance in the treatment of the disease. I think one may go so far as to say that in every focus that is satisfactorily drained the infection by actinomyces will be promptly checked, for this organism, although it can propagate in the fluid of an abscess cavity (which has lost much of its antitryptic power) cannot do so in the unaltered lymph.

This being the case, I would suggest that the principles of treatment advocated by Sir Almroth Wright[10] in connexion with wound infections should be employed here, the incisions being followed up by the intermittent application (every 2-3 hours) of hypertonic salt solution (3–5 per cent.) in order to promote a free flow of lymph through, and out of, the infected tissues. This treatment should be discontinued after a few days in order to facilitate healing.

What we learned in connexion with curetting was that this operation should not be performed with a sharp instrument—which opens up uninfected tissues—but with a dry gauze swab. There is in actinomycosis a fairly sharp line of demarcation between the uninfected and the infected tissues, and since the latter, in process of erosion, are very friable, it is usually possible to remove them almost in toto on a swab, leaving the wound with so little infection that it can easily be dealt with by the leucocytes. In one of the later cases of the series here reported an abscess nearly as large as a closed fist was treated in this way after incision and forthwith sewn up. It healed by first intention in a week.

I would therefore emphasise two points in connexion with the surgery of the disease: first, the necessity of maintaining efficient drainage throughout the course of the illness; and secondly, dry curetting by means of a gauze swab. The question, of course, arises as to how far these measures are applicable to abdominal and thoracic cases, when, as is frequently the case, the diagnosis has been made only after the infection has extended considerably beyond the original focus. It seems to the writer that, by the aid of stereoscopic skiagrams taken after the injection under pressure of a bismuth suspension, one might be able in such cases to trace the chief ramifications of the infective process, and thereafter proceed to deal with each of these by curetting and "salt suction" as above described. An extensive operation of this kind would seem to be justifiable in view of the very high mortality attaching to these cases.

TREATMENT BY VACCINES.

Several considerations led us to hope for success in the treatment of these infections by active immunisation. In the first place, actinomycosis is a disease which progresses but slowly, and does not, as a rule, seriously injure the patient's general health for a considerable period; there is, therefore, if the diagnosis is made fairly early, abundant opportunity for a satisfactory response to the inoculations of vaccine. Again, the disease shows a tendency to spontaneous cure, given a satisfactory outflow for collections of pus. This circumstance presumably stands in relation to the fact that the organism is unable to grow in the unaltered blood fluids and is readily ingested by the leucocytes. It is probable, therefore, that even a small response to the inoculation of vaccines would suffice to turn the scale against the progress of the infection.

Up to the present the writer has treated some 23 cases by this method, always in association with simple surgical measures, as outlined above. In all cases a vaccine prepared from strains of *Actinomyces bovis* of human origin was employed, and most of them received in addition other vaccines corresponding to their respective secondary infections. Autogenous actinomyces vaccines were used for 11 cases, most of the remainder being treated by the polyvalent stock vaccine prepared at St. Mary's Hospital and issued by Messrs. Parke, Davis and Co. Standardisation of the vaccines was carried out by making approximate counts of their mycelial fragments after the growths had been broken up by forcible shaking. Since this breaking up, however, is at best very imperfect, there is much to be said in favour of abandoning the method of enumeration by counting and replacing it by the procedure employed for the issue of tuberculin (bacillary emulsion)—viz., grinding an ascertained weight of dried culture. The writer has adopted this latter practice since the war. A considerable growth of the organism was obtained by inoculating a pure culture into one or more Erlenmeyer flasks of glucose broth under oil; when fully grown the supernatant fluid of these flasks was decanted, the deposit of actinomyces was collected, washed, and then dried over sulphuric acid in vacuo, the dry flakes being finally ground in a Hayden mortar and emulsified in saline. That actinomyces vaccines so prepared are capable of acting as satisfactory antigens was demonstrated by the inoculation of rabbits, which responded in every case by a development of agglutinins.

Some Particulars with Regard to the Treatm Vaccines.

An attempt was first made to control t actinomyces vaccine by measurements of opsonic power, using for this purpose a organism which had acquired a largely of growth on artificial media. The phag tions so obtained were not all that c but they afforded a rough indication that the appropriate dose was about 5-10 millions of mycelial fragments. Proceeding on this basis we have generally commenced the treatment with doses of 2 or 2½ million fragments at intervals of five days, and gradually increased the quantity as guided by the progress of the patient. The best results have usually been obtained with doses of from 4-10 million fragments. In a few cases which were not improving on smaller doses the quantity has been considerably increased—in one case to 75 million fragments—but without any apparent advantage.

Reaction.—In several instances the inoculation of vaccine was followed by a rise of temperature, but this did not occur with regularity in any patient. As a rule there was no constitutional disturbance of any kind, the actinomycotic focus showed no increased congestion, and at the site of inoculation there was no appreciable reaction.

Treatment of the associated infections by the appropriate vaccines.—In an earlier report on "The Mycelial and other Micro-organisms Associated with Actinomycosis"[1] the writer has called attention to a small cocco-bacillary microbe which is frequently to be found in great numbers along with actinomyces in the actinomycotic granule. This microbe has been described previously by Klinger[11] under the name *Bacterium actinomycetum comitans.* The significance of its association with the mycelial organism in actinomycosis is far from clear at present (the question is discussed at some length in the paper referred to), but it was hoped that something might be gained by combining inoculations of a vaccine of this bacterium with that of actinomyces. Twelve of the patients were so inoculated, the doses of vaccine varying from 5 to 400 millions of the bacterium. As in the case of actinomyces vaccine, the inoculations of this bacterium did not as a rule give rise to any appreciable reactions. The more common secondary infections, such as those by staphylococci, streptococci, diphtheroid and coliform bacilli, were also combated by the appropriate vaccines.

The Results of Vaccine Treatment.

The inoculated cases comprise: 11 cervico-facial infections, with which may be included 1 of the hand; 6 thoracic infections; 6 abdominal infections. The first group—of 11 cases—included two which were decidedly unfavourable to any treatment. One of these was a girl who had symptoms of intracranial pressure before admission to hospital (ten months from the onset of the disease), and died in a short time with a large temporo-sphenoidal abscess. The second was that of the man previously mentioned, in whom the disease had involved a large part of the mandible. Mr. Cope performed an extensive resection from which the patient made an apparently complete recovery and was able to join the army. Recently, however, the disease recurred in a very small focus in front of the ear, but the patient is again under vaccine treatment and the infection is making no headway.

The remaining nine cases of this group were of lesser degrees of severity, but in most of them the infection had been in progress for several months before they came under treatment. All recovered, and have not, so far as I have been able to ascertain, had any recurrence during the 4-6 years that have elapsed. In the least extensive cases a period of 3-6 weeks sufficed for cure, but in others a much longer time was required and many inoculations. Whenever bone was involved the recovery was very slow.

Of the six thoracic cases none have been saved. In considering this melancholy failure it should be made clear that in all of them the disease had made considerable headway before vaccine treatment was instituted. In one case 10 months had intervened since the symptoms were first noticed, and in the other cases 8, 7, 5, 3, and 3 months respectively. One case was particularly disappointing, but his record is not without grounds for hope.

With regard to the six abdominal cases much the same considerations apply. The five of them who died had been ill for 13, 8, 6, 5, and 5 months respectively before they were transferred to us for treatment. Three of them had already the cachexia and the particularly offensive discharge which are so often associated with this condition when it attacks the abdomen, and which are presumably due to a very severe secondary infection. (So far we have not been able to determine which particular microbe or microbes are responsible for the smell.) In these five cases one cannot say that anything was achieved by treatment. The sixth case was less severe than the others. The infection had been recognised about eight weeks after the original operation by Mr. Cope for appendicular abscess, and although there was irregular fever—sometimes to 102° F.—the cachexia and the offensive discharge never developed. Thanks to a small perforation of the ileum which developed early in the course of the disease we were enabled in this case to secure favourable drainage by means of a counter opening in the buttock. It is difficult to decide how much of the credit for her recovery should be allotted to vaccine treatment, and how much to this efficient drainage. Probably each factor was of importance. (This patient's recovery suggests that it might prove worth while in similar circumstances to secure favourable drainage by trephining the ileum from behind.)

CONCLUSIONS WITH REGARD TO VACCINE TREATMENT.

The opinion I have formed from my experience up to date is as follows: the treatment of actinomycosis by vaccines facilitates recovery when efficient surgical drainage of the affected tissues is secured and maintained; when, however, drainage is unsatisfactory the use of appropriate vaccines will not usually suffice to stay the progress of the infection. In support of the first part of this opinion I am unable to offer any evidence which will carry conviction on paper—it is manifestly difficult when dealing with a condition like cervico-facial actinomycosis, which tends to recover spontaneously if drained, to be certain that cure has been hastened by any indirect therapeutic measures. In three or four of my cases, however, which had hung fire for several weeks or months, improvement took place so promptly and so rapidly after the commencement of inoculations that there seemed to be no doubt as to the efficacy of the treatment, and this opinion found further support from the case of thoracic infection whose story has been told above.

With reference to the failure of vaccine treatment in cases whose lesions are not satisfactorily drained I would suggest that this may be due in a large part to the blood stream having very little access to those lesions by reason of the zone of "wooden" induration which habitually surrounds them.

The patient, a school teacher of 43, was sent to Sir Almroth Wright by Sir John Collie. Two months previously he had been operated on by Mr. J. Sherren at the London Hospital for an extraperitoneal abscess in the left iliac fossa and another abscess over the left shoulder. In spite of treatment by potassium iodide, further lesions had developed on the back of the neck, the shoulder, and the left costal margin, and the man was very ill on admission to St. Mary's. The lesion on the costal margin suggested the probable existence of a pulmonary focus, but definite evidence of this was not obtained at that time. From the first inoculation of vaccine he began to improve rapidly, his fever subsided, and several of the lesions healed. After four months he was permitted to resume his work, which he carried on for some three years, although one or two small lesions were never quite dried up. Sir John Collie[12] wrote enthusiastically of the progress he had made. Unhappily the cure was not so complete as we hoped at that time. Although he was an excellent patient and continued faithfully with the inoculations over a very long period, the pulmonary lesion reasserted itself four and a half years after the onset and he went down hill. Judging from the clinical course of the other thoracic cases, and taking into account his serious condition when he came under treatment, it seems legitimate to suppose that without vaccines this man would have succumbed within 18 months from the commencement of the disease—probably within a year. Why we were able to achieve so much in his case, and finally failed, is not clear. In part it may have been due, as he himself thought, to his becoming very depressed over personal war anxieties.

It will be noticed that my failure to secure good results in most of the thoracic cases contrasts unfavourably with the striking cure reported by Dr. Wynn (1908).[13] Fortunately, Dr. Wynn described in some detail the characters of the streptothrix infecting his case, and on examining his record it becomes clear that he had to deal with quite a different infection from that with which the present writer is here concerned. That being the case, we cannot properly contrast the results of vaccine treatment in the two infections.

The points on which is based the opinion that Dr. Wynn's streptothrix was not *Actinomyces bovis* (Wolff-Israel) are the following:—

(1) The record says: "The pus or sputum, when stained by Gram's method, showed enormous numbers of delicate, thread-like filaments of fairly uniform thickness." In infections by *Actinomyces bovis*, such as the writer's cases, it has been quite exceptional to find mycelial elements free in the pus; they are almost entirely confined to the granules, and, unless one of these is consciously crushed, the threads will not become disseminated in preparing a film of pus or sputum. Occasionally, of course, one may chance to find a microscopic cluster of threads, presumably an embryo "granule."

(2) "Numerous spores were seen, but no clubs." In none of the writer's cases were spores seen, nor in the 13 cases reported by Homer Wright.[14] Clubs were found whenever they were looked for—i.e., in rather more than 75 per cent. of my cases.

(3) In describing its cultural characters Dr. Wynn says of his organism: "It grows readily on ordinary media at 37° C., much less readily at room temperature. It grows under both aerobic and anaerobic conditions, but more freely under the former." Here are three points in which the organism contrasts with *Actinomyces bovis*. The latter does not grow readily on ordinary media; does not grow at all at room temperature; and, although it will occasionally give a very sparse growth under aerobic conditions it is decidedly an anaerobic organism.

(4) Again, Dr. Wynn found that at 37° C. growth appeared after 24 hours on agar. Cultures of *Actinomyces bovis* very seldom appear before three days on agar—more commonly not until 4-6 days.

With regard to gelatin stabs, Dr. Wynn's record says, "Growth slower, but after four days discoid colonies form." *Actinomyces bovis* will not grow at all in solid gelatin.

The three or four cases I have seen of infection by streptothrices other than *Actinomyces bovis* have been of decidedly milder clinical type than those of thoracic and abdominal actinomycosis.

SHOULD AN AUTOGENOUS OR A POLYVALENT STOCK VACCINE OF ACTINOMYCES BE EMPLOYED?

The answer to this question turns chiefly on considerations of the degree of difference found to exist between individual strains of *Actinomyces bovis*. The 21 strains isolated in pure culture by the author have shown a close conformity in respect of their cultural characters, viability, and staining reactions. Their morphology has not been minutely studied, but no gross differences have been observed—apart from a somewhat unequal tendency to assume a bacillary habit of growth in subcultures. On the other hand, it has been suggested by the result of some few agglutination tests that the species *Actinomyces bovis* comprises more than one serological type. The following is a record of one such agglutination test:—

Three rabbits were inoculated with typical strains of *Actinomyces bovis*—viz., "G1," "G4," and "Arthur" respectively. When their sera were tested against emulsions of the three strains the agglutination observed was as shown in Table II. (A, B, C).

In view of these findings—the agreement in respect of general cultural characters and the divergence in regard to serological type—it would seem probable that a stock vaccine would serve as well as an autogenous one if, at any rate, it included representatives of the different types. But this latter condition is not easy of realisation at present, for the determination of types can only be slowly accomplished as a considerable number of strains accumulate for study. For the time being, therefore, I think that an autogenous vaccine should be employed whenever practicable, but, since a period of three to four weeks will often be necessary for its preparation, treatment should always be *commenced* with a polyvalent stock vaccine.

TABLE II.—(A) *Rabbit Inoculated with Emulsion of Strain "G 1."*

Serum.	Dilutions of serum.				
	1 : 50	1 : 100	1 : 200	1 : 400	1 : 800
Strain "G1"	+++	+++	++	+	Trace.
" "Arthur" ...	+	+	0	0	...
" "G4"	++++	++++	+++	++	...

(B) *Rabbit Inoculated with Emulsion of Strain "Arthur."*

Serum.	1 : 50	1 : 100	1 : 200	1 : 400	1 : 800
Strain "Arthur" ...	++++	+	0	0	0
" "G1"	+++	++	0	0	0
" "G4"	++++	+++	++	Trace.	...

(C) *Rabbit Inoculated with Emulsion of Strain "G 4."*

Serum.	1 : 50	1 : 100	1 : 200	1 : 400	1 : 800
Strain "G4"	++++	++++	+++	+++	++
" "G1"	Trace.	0	0	...	...
" "Arthur" ...	0	0	0	0	...

+++, ++, + = Incomplete agglutination, of varying degrees.
++++ = Complete agglutination. 0 = No agglutination.

DISCUSSION.

(1) CONCERNING THE TERM ACTINOMYCOSIS.

There is, unfortunately, a great deal of confusion with regard to the use of this term. In what follows I shall try to show that under it have been included in the past at least four classes of cases. As a consequence our knowledge of these infections has become less, rather than more exact, and progress in the direction of better treatment has been undoubtedly handicapped. The recent application of vaccine therapy to these cases makes it particularly desirable that we should deal, as far as possible, with homogeneous groups of cases, and give to these groups distinguishing names. Lignières and Spitz,[15] recognising the need for a more precise nomenclature, have suggested that it would be well to abandon altogether the old term and substitute for it "actinophytose," adding specific subtitles for the several classes of cases. There is something to be said for this proposal, but more, I think, in favour of retaining the older term, to be used in a definitely restricted sense, and of introducing one or two new terms for the infections which are separated off by those restrictions. We may now consider what restrictions it might be well to put upon the term actinomycosis.

The origin of this term dates back to the discovery of the well-known radiating arrangement of "clubs" round the "sulphur granules" derived from certain granulomatous lesions of cattle and of man. So far as was known at that time such granules were always composed of a feltwork of branching mycelium. It is readily understood, then, that the presence of "granules" came to be regarded as diagnostic and pathognomonic of actinomycosis. When, with the introduction of artificial media, cultures were obtained from some of these infections, several quite distinct organisms were reported by different investigators, the types which attracted most attention being (1) an easily grown, aerobic variety, described by Boström[16] and others; and (2) an anaerobic variety, grown with difficulty, described by Wolff and Israel.[17] In view of these discordant results of the earlier bacteriological work it came to be believed that there was no one infective agent responsible for actinomycosis, but that several more or less allied micro-organisms could produce the disease.

The work of the past 20 years, however, has brought to light two facts which require us to recast the earlier views. It has shown (1) that the production of granules with clubs is not pathognomonic of actinomycosis; the same thing occurs in various conditions which are not mycoses at all but bacillary infections, and sometimes is associated with clinical conditions totally different from those of actinomycosis. (2) That of all the human infections which are productive of "granules" and show the well-known clinical features of actinomycosis, the great majority are due to one and the same mycelial species—viz., that described by Wolff and Israel.[17]

It will be conducive to clearness if we consider these two statements separately. Beginning with the first, the evidence that granules are formed in conditions other than actinomycosis is as follows: Lignières and Spitz[18] have described an infection of cattle which gives rise to granulomatous tissue not unlike those of actinomycosis, but in which the "sulphur granules" (showing typical clubs) are composed entirely of Gram-negative bacilli. They gave the name "actinobacillose" to this condition and that of "*actinobacille*" to the microbe. These authors state that this infection is widely spread in the world. Nocard[19] reported cases in France in 1902, and in 1915 Griffith,[20] examining so-called actinomycotic material (chiefly tongues) derived from cattle killed in England, made the important discovery that no less than 40 out of 44 specimens presented lesions which were apparently due to this bacillus and not to a mycotic infection. So far as I am aware, only one human case has been reported (Ravaut and Pinoy,[12] 1911).

Apart from actinobacillosis it is well known that the injection of tubercle bacilli will, in certain circumstances, give rise to club formation around the masses of bacilli. Further, Lignières and Spitz[15] state that granules with clubs ("massues rayonnées") may occur in animal infections produced by various other microbes—e.g., by the butter bacillus of Rabinowitsch, the bacillus of Cozzolino, the hay bacillus of Möller, &c. Quite recently a very interesting human infection associated with the production of granules has come to my notice through the kindness of Miss Aldrich Blake and Dr. Lepper, by whose permission I am enabled to refer to it. A young woman was admitted to the Elizabeth Garrett Anderson Hospital with a tumour in the left loin which proved to be an abscess connected with a tuberculous kidney. The pus evacuated from this abscess showed a large number of granules, similar in size and naked-eye appearance to those of actinomycosis. Under the microscope, however, no clubs could be seen nor any mycelium—the granules were composed of masses of Gram-negative bacilli, 2·5–5μ in length and about 0·6μ in thickness. An organism corresponding to these bacilli was cultivated aerobically on agar, growth occurring in 24–48 hours in the form of flat, semi-transparent colonies of about 1½ millimetres diameter. It is a facultative anaerobe, does not grow at room temperature, and has not been observed to form spores. It is actively motile, and is not acid-fast. I have been unable to identify this organism, which seems to be quite distinct from the *actinobacille* of Lignières and Spitz.

From the fact that this bacillus had disappeared from the pus within a week of the first drainage operation I conclude that it was probably a saprophytic invader of the abscess cavity.

We may pass now to the statement that the great majority of actinomycotic infections are due to one microbic species—viz., the anaerobic type *Actinomyces bovis*† described by Wolff and Israel.[17] The data relating to that conclusion may conveniently be set out in the form of a table (Table III.) showing the more important of the records of bacteriological investigations made during the past 20 years.

It will be seen from Table III. that in seven different parts of the world one and the same type of mycelial organism—viz., that described by Wolff and Israel (1891)[17]—has played a predominant part in the actinomycotic infections both of man and cattle. (That this was not recognised from the first is, no doubt, largely due to the circumstance that methods of anaerobic cultivation were but little developed and applied when the earliest observations were made.) From a very small minority of cases quite different organisms were cultivated. In two instances at least these were aerobic species, and it seems not improbable that they were present merely as air-borne contaminations. Whether that was the case or not, it is important to note that isolated instances are on record in which it seems clear that an aerobic mycelial organism productive of typical granules in vivo has given rise to suppurative lesions—e.g., Wynn's case referred to above and that of de Nooy[27] recently reported from Java.

It should be particularly noted that the bacteriological findings summarised have reference only to infections which yielded typical "granules" in the discharges. The results would have shown much less uniformity had the several investigations included in their purview all those cases in which Gram-staining mycelium—irrespective of its aggregation into naked-eye granules—was present in the discharges.

TABLE III.

(A) Number of cases from which cultures were obtained and the type of mycelial organism determined.

(B) Number of cases from which *Actinomyces bovis* (Wolff-Israel) was cultivated: It is not claimed that the description given by each investigator for the strains included in this column tallies exactly with that of Wolff and Israel. There is, unfortunately, at present no touchstone by which to decide unequivocally whether a given strain is or is not identical with the type Wolff-Israel. The figures given should, therefore, be taken to mean that each investigator himself regarded so many of his strains as showing a general correspondence with that type.

(C) Number of cases from which an anaerobic mycelial organism quite distinct from *Actinomyces bovis* was cultivated.

(D) Number of cases from which an aerobic mycelial organism was cultivated.

Name of investigator, date of publication, and country in which the cases occurred.	Infections of man.				Infections of cattle.

(*a*) The character of the one remaining strain not described.
(*b*) One strain not identified.
(*c*) It is doubtful whether these two strains were really distinct from *Actinomyces bovis* or merely variants of that type. They showed slight differences in respect of their cultural characters, but owing to pressure of other work were not fully investigated.
(*d*) A single colony of the mycelial organism was cultivated from this case.

With this summary of new knowledge in mind we may come back to deal with the problem of nomenclature. There appear to be four classes of cases which it is desirable to define and to distinguish by different names. They are:—

(*a*) *Cases which show granules composed of Gram-staining mycelium, and from which a micro-organism of the type* Actinomyces bovis (*Wolff-Israel*) *is isolated by culture.* To this class, which will be by far the largest of all the granule infections—in man, at any rate—I should restrict the term actinomycosis.

(*b*) *Cases which show granules composed of Gram-staining mycelium, but this mycelial organism proves on cultivation to be distinct from the type* Actinomyces bovis (*Wolff-Israel*). For this class, which I think to be a small one, I would propose the term "Paractinomycosis." The cases reported by Wynn[13] and de Nooy[26] were of this kind.

(*c*) *Cases which show granules composed, not of mycelium, but of bacillary organisms.* For these the term Actinobacillosis, proposed by Lignières and Spitz, might well be retained, adding, whenever possible, a specific subtitle to denote the particular bacillus in question.

(*d*) *Cases which show an infection by a Gram-staining mycelial organism, but the mycelium is not aggregated into granules visible to the naked eye.* To this class, which I take to be a heterogeneous, and not a very small, one, a name with the prefix "actino" would seem to be inappropriate. The term streptothricosis, which has frequently been employed to designate these cases in the past, might well be retained, and a specific subtitle appended to it whenever the particular infecting agent can be identified with a recognised type of organism.

When, as will often happen, attempts to cultivate the mycelium from a case with typical granules are either not made or are not successful it would seem justifiable—in view of the findings shown in Table III.

---

† In adopting the name *Actinomyces bovis* for this type I follow the usage which seems to have the most general support. Some writers, including Lignières and Spitz, have held that the name properly belongs to the quite different aerobic organism described by Boström and others.

—to label the case provisionally as one of actinomycosis. For the purposes of scientific records, on the other hand, the isolation of the organism is, in my opinion essential.

WHAT IS THE SOURCE OF INFECTION IN ACTINOMYCOSIS?

The answer to this question is given—either definitely stated or implied—in every surgical and veterinary textbook. But is it true? The "ray fungus," we are told, has its habitat in soil, on grain, straws, and other vegetable matter and is conveyed by these to the tissues of man and animals. This belief is chiefly due to the authority of Boström,[16] who, in 1891, published a report of a laborious investigation on the subject. He observed that cattle grazing in marshy districts frequently developed actinomycosis, and that moulds were met with on the vegetation of such districts, which showed some resemblance to certain mycelial organisms which had occasionally been cultivated from actinomycotic discharges. (For criticism of this latter part of the work see Homer Wright's paper.[14]) Further, on examining the mouths of cattle Boström noticed that particles of vegetable matter were very frequently lodged down between the teeth and gums, and he concluded that these particles probably carried the infection into the tissues. By means of serial sections he succeeded in demonstrating minute fragments of vegetable matter (barley "whiskers") in several instances, and he reports in detail the case of a woman who developed a submaxillary abscess, in the pus of which a similar tiny particle of barley (1 × 0·2 mm.) was detected.

This chain of evidence is not, however, very satisfactory when looked at from the standpoint of to-day. We now know, as has been shown above, that an anaerobic species (*Actinomyces bovis*), and not the organism described by Boström, is most commonly the infecting agent in actinomycosis, of man at any rate. Secondly, *Actinomyces bovis* has never, so far as I am able to ascertain, been met with outside the animal body. There are many species of actinomycetes recoverable from soil, but all appear to be aerobic organisms with characters quite different from those of *Actinomyces bovis*. Harbitz[25] reports an attempt of Hagen to recover the latter organism from "natural" sources in a part of Norway where actinomycosis was fairly common. He investigated 9 strains of mycelial organisms (3 obtained from the air, 2 from straw, 3 from barley and oats, and 1 from manure), but all were compulsory aerobes. Thirdly, *Actinomyces bovis* is a very delicate organism, which grows only at temperatures near that of the human body and very sparsely, if at all, in the presence of air; it also dies out very readily, especially when dried, and has not been shown to form spores. Having these characters, there is little likelihood that it has its "natural" habitat outside the human and animal body. Again, it is, perhaps, significant that the incidence of actinomycosis seems to be no greater among the agricultural population than among town-dwellers; and women are affected almost as frequently as men. Finally, it may be remarked that only in a very small percentage of cases is there any record of a vegetable foreign body having been evacuated from the primary abscess or a history which suggests the probability of this mode of infection. Only one of the author's 25 cases had such a history.

In view of all the above considerations it seems highly improbable that infection is usually conveyed to man in the manner suggested by Boström. At the same time one must acknowledge that there are a fair number of well-attested cases on record in which infection seems definitely to have followed the impaction of vegetable material. To cite only two—there is the case reported by Soltman (quoted by Poncet and Berard,[9] p. 42) of a boy who swallowed a head of barley which apparently stuck in his œsophagus and later worked its way out through an abscess in the sixth intercostal space, and another instance which occurred in my own experience of a piece of grass being evacuated from the [illegible] boy. The grass was said to [illegible] month previously.

(It may be noted that the one case described at length by Boström in support of his thesis was apparently not a genuine actinomycosis, for he expressly mentions that there were no granules or clubs, and the mycelium was distributed freely in the pus.)

With regard to cases of this kind, two considerations suggest themselves. Firstly, it may happen that an infection is sometimes introduced into the tissues on grain, straws, &c., but that the infecting organism so introduced is something other than *Actinomyces bovis*. This was probably so in Boström's case just referred to. In the second place, Homer Wright has pointed out that the development of actinomycosis following the impaction of a piece of straw, grain, &c., in the mucous membrane does not necessarily imply that the infecting organism was conveyed on that foreign body. It is conceivable that the impaction merely favoured infection by an organism which was pre-existing as a saprophyte in the mouth or other part of the alimentary tract. That actinomyces may at times be present in the mouth of a normal individual was strongly suggested by the history of a case which Mr. Cope has reported (vide Case 13 of his series).[2] This patient injured the knuckles of his hand by contact with an opponent's teeth. An acute cellulitis ensued, and was followed by the development of a typical, indolent, actinomycotic lesion, which persisted for three months before he came to the hospital. A similar case has been reported by McWilliams[28] in America. Further evidence has been furnished by Lord.[29] Having observed fragments of Gram-staining mycelium resembling actinomyces in the contents of carious teeth and tonsillar crypts (of patients free from actinomycosis) he made an emulsion of these and inoculated it into laboratory animals. Small lesions were produced which showed on section the formation of actinomycotic granules. Unfortunately he did not complete the investigation by the isolation of actinomyces from these lesions. Further observations of this kind should go far towards resolving the problem.

My thanks are due to Sir Almroth Wright for permission to publish this report, and for much help and encouragement throughout the work; also to Mr. V. Z. Cope for his valuable coöperation in the treatment of many of the cases.

PLAGUE IN SOUTH AFRICA.—Several deaths of natives from plague have occurred in the Orange Free State during March. Bacteriological examinations have confirmed the diagnosis. The infection exists amongst, and is being perpetuated and spread by, wild rodents, and possibly also, it is stated, by small carnivora, such as the muishond and meerkat, the flea being the connecting link with man in the chain of infection.

the well-known *clinical features of actinomycosis*, the great majority are due to one and the same mycelial species—viz., that described by Wolff and Israel.[17]

It will be conducive to clearness if we consider these two statements separately. Beginning with the first, the evidence that granules are formed in conditions other than actinomycosis is as follows: Lignières and Spitz[18] have described an infection of cattle which gives rise to granulomatous tissue not unlike those of actinomycosis, but in which the "sulphur granules" (showing typical clubs) are composed entirely of Gram-negative bacilli. *They gave the name* "*actinobacillose*" to this condition and that of "*actinobacille*" to the microbe. These authors state that this infection is widely spread in the world. Nocard[19] reported cases in France in 1902, and in 1915 Griffith,[20] examining so-called actinomycotic material (chiefly tongues) derived from cattle killed in England, made the important discovery that no less than 40 out of 44 specimens presented lesions which were apparently due to this bacillus and not to a mycotic infection. So far as I am aware, only one human case has been reported (Ravaut and Pinoy,[12] 1911).

Apart from actinobacillosis it is well known that the injection of tubercle bacilli will, in certain circumstances, give rise to club formation around the masses of bacilli. Further, Lignières and Spitz[15] state that granules with clubs ("massues rayonnées") may occur in animal infections produced by various other microbes—e.g., by the butter bacillus of Rabinowitsch, the bacillus of Cozzolino, the hay bacillus of Möller, &c. Quite recently a very interesting human infection associated with the production of granules has come to my notice through the kindness of Miss Aldrich Blake and Dr. Lepper, by whose permission I am enabled to refer to it. A young woman was admitted to the Elizabeth Garrett Anderson Hospital with a tumour in the left loin which proved to be an abscess connected with a tuberculous kidney. The pus evacuated from this abscess showed a large number of granules, similar in size and naked-eye appearance to those of actinomycosis. Under the microscope, however, no clubs could be seen nor any mycelium—the granules were composed of masses of Gram-negative bacilli, 2·5–5μ in length and about 0·6μ in thickness. An organism corresponding to these bacilli was cultivated aerobically on agar, growth occurring in 24–48 hours in the form of flat, semi-transparent colonies of about 1½ millimetres diameter. It is a facultative anaerobe, does not grow at room temperature, and has not been observed to form spores. It is actively motile, and is not acid-fast. I have been unable to identify this organism, which seems to be quite distinct from the *actinobacille* of Lignières and Spitz.

From the fact that this bacillus had disappeared from the pus within a week of the first drainage operation I conclude that it was probably a saprophytic invader of the abscess cavity.

We may pass now to the statement that the great majority of actinomycotic infections are due to one microbic species—viz., the anaerobic type *Actinomyces bovis*[†] described by Wolff and Israel.[17] The data relating to that conclusion may conveniently be set out in the form of a table (Table III.) showing the more important of the records of bacteriological investigations made during the past 20 years.

It will be seen from Table III. that in seven different parts of the world one and the same type of mycelial organism—viz., that described by Wolff and Israel (1891)[17]—has played a predominant part in the actinomycotic infections both of man and cattle. (That this was not recognised from the first is, no doubt, largely due to the circumstance that methods of anaerobic cultivation were but little developed and applied when the earliest observations were made.) From a very small minority of cases quite different organisms were cultivated. In two instances at least these were aerobic species, and it seems not improbable that they were present merely as air-borne contaminations. Whether that was the case or not, it is important to note that isolated instances are on record in which it seems clear that an aerobic mycelial organism productive of typical granules *in vivo* has given rise to suppurative lesions—e.g., Wynn's case referred to above and that of de Nooy[27] recently reported from Java.

It should be particularly noted that the bacteriological findings summarised have reference only to infections which yielded typical "granules" in the discharges. The results would have shown much less uniformity had the several investigations included in their purview all those cases in which Gram-staining mycelium—irrespective of its aggregation into naked-eye granules—was present in the discharges.

TABLE III.

(*a*) The character of the one remaining strain not described.
(*b*) One strain not identified.
(*c*) It is doubtful whether these two strains were really distinct from *Actinomyces bovis* or merely variants of that type. They showed slight differences in respect of their cultural characters, but owing to pressure of other work were not fully investigated.
(*d*) A single colony of the mycelial organism was cultivated from this case.

With this summary of new knowledge in mind we may come back to deal with the problem of nomenclature. There appear to be four classes of cases which it is desirable to define and to distinguish by different names. They are:—

(*a*) *Cases which show granules composed of Gram-staining mycelium, and from which a micro-organism of the type* Actinomyces bovis (*Wolff-Israel*) *is isolated by culture.* To this class, which will be by far the largest of all the granule infections—in man, at any rate—I should restrict the term actinomycosis.

(*b*) *Cases which show granules composed of Gram-staining mycelium, but this mycelial organism proves on cultivation to be distinct from the type* Actinomyces bovis (*Wolff-Israel*). For this class, which I think to be a small one, I would propose the term "Paractinomycosis." The cases reported by Wynn[13] and de Nooy[26] were of this kind.

(*c*) *Cases which show granules composed, not of mycelium, but of bacillary organisms.* For these the term Actinobacillosis, proposed by Lignières and Spitz, might well be retained, adding, whenever possible, a specific subtitle to denote the particular bacillus in question.

(*d*) *Cases which show an infection by a Gram-staining mycelial organism, but the mycelium is not aggregated into granules visible to the naked eye.* To this class, which I take to be a heterogeneous, and not a very small, one, a name with the prefix "actino" would seem to be inappropriate. The term streptothricosis, which has frequently been employed to designate these cases in the past, might well be retained, and a specific subtitle appended to it whenever the particular infecting agent can be identified with a recognised type of organism.

When, as will often happen, attempts to cultivate the mycelium from a case with typical granules are either not made or are not successful it would seem justifiable—in view of the findings shown in Table III.

[†] In adopting the name *Actinomyces bovis* for this type I follow the usage which seems to have the most general support. Some writers, including Lignières and Spitz, have held that the name properly belongs to the quite different aerobic organism described by Boström and others.

—to label the case provisionally as one of actinomycosis. For the purposes of scientific records, on the other hand, the isolation of the organism is, in my opinion, essential.

(2) WHAT IS THE SOURCE OF INFECTION IN ACTINOMYCOSIS?

The answer to this question is given—either definitely stated or implied—in every surgical and veterinary textbook. But is it true? The "ray fungus," we are told, has its habitat in soil, on grain, straws, and other vegetable matter and is conveyed by these to the tissues of man and animals. This belief is chiefly due to the advocacy of Boström,[16] who, in 1891, published a report of a laborious investigation on the subject. He observed that cattle grazing in marshy districts frequently developed actinomycosis, and that moulds were met with on the vegetation of such districts, which showed some resemblance to certain mycelial organisms which had occasionally been cultivated from actinomycotic discharges. (For criticism of this latter part of the work see Homer Wright's paper.[14]) Further, on examining the mouths of cattle Boström noticed that particles of vegetable matter were very frequently forced down between the teeth and gums, and he concluded that these particles probably carried the infection into the tissues. By means of serial sections he succeeded in demonstrating minute fragments of vegetable matter (barley "whiskers") in several instances, and he reports in detail the case of a woman who developed a submaxillary abscess, in the pus of which a similar tiny particle of barley (1 × 0·2 mm. was detected.

This chain of evidence is not, however, very satisfactory when looked at from the standpoint of to-day. We now know, as has been shown above, that an anaerobic species (*Actinomyces bovis*), and not the organism described by Boström, is most commonly the infecting agent in actinomycosis, of man at any rate. Secondly, *Actinomyces bovis* has never, so far as I am able to ascertain, been met with outside the animal body. There are many species of actinomycetes recoverable from soil, but all appear to be aerobic organisms with characters quite different from those of *Actinomyces bovis*. Harbitz[25] reports an attempt of Hagen to recover the latter organism from "natural" sources in a part of Norway where actinomycosis was fairly common. He investigated 9 strains of mycelial organisms (3 obtained from the air, 2 from straw, 3 from barley and oats, and 1 from manure), but all were compulsory aerobes. Thirdly, *Actinomyces bovis* is a very delicate organism, which grows only at temperatures near that of the human body and very sparsely, if at all, in the presence of air; it also dies out very readily, especially when dried, and has not been shown to form spores. Having these characters, there is little likelihood that it has its "natural" habitat outside the human and animal body. Again, it is, perhaps, significant that the incidence of actinomycosis seems to be no greater among the agricultural population than among town-dwellers; and women are affected almost as frequently as men. Finally, it may be remarked that only in a very small percentage of cases is there any record of a vegetable foreign body having been evacuated from the primary abscess or a history which suggests the probability of this mode of infection. Only one of the author's 25 cases had such a history.

In view of all the above considerations it seems highly improbable that infection is usually conveyed to man in the manner suggested by Boström. At the same time one must acknowledge that there are a fair number of well-attested cases on record in which infection seems definitely to have followed the impaction of vegetable material. To cite only two—there is the case reported by Soltman (quoted by Poncet and Berard,[9] p. 42) of a boy who swallowed a head of barley which apparently stuck in his œsophagus and later worked its way out through an abscess in the sixth intercostal space, and another instance which occurred in my own experience of a piece of grass being evacuated from the submaxillary abscess of a boy. The grass was said to have "stuck in his throat" about a month previously. (It may be noted that the one case described at length by Boström in support of his thesis was apparently not a genuine actinomycosis, for he expressly mentions that there were no granules or clubs, and the mycelium was distributed freely in the pus.)

With regard to cases of this kind, two considerations suggest themselves. Firstly, it may happen that an infection is sometimes introduced into the tissues on grain, straws, &c., but that the infecting organism so introduced is something other than *Actinomyces bovis*. This was probably so in Boström's case just referred to. In the second place, Homer Wright has pointed out that the development of actinomycosis following the impaction of a piece of straw, grain, &c., in the mucous membrane does not necessarily imply that the infecting organism was conveyed on that foreign body. It is conceivable that the impaction merely favoured infection by an organism which was pre-existing as a saprophyte in the mouth or other part of the alimentary tract. That actinomyces may at times be present in the mouth of a normal individual was strongly suggested by the history of a case which Mr. Cope has reported (vide Case 13 of his series).[3] This patient injured the knuckles of his hand by contact with an opponent's teeth. An acute cellulitis ensued, and was followed by the development of a typical, indolent, actinomycotic lesion, which persisted for three months before he came to the hospital. A similar case has been reported by McWilliams[28] in America. Further evidence has been furnished by Lord.[29] Having observed fragments of Gram-staining mycelium resembling actinomyces in the contents of carious teeth and tonsillar crypts (of patients free from actinomycosis) he made an emulsion of these and inoculated it into laboratory animals. Small lesions were produced which showed on section the formation of actinomycotic granules. Unfortunately he did not complete the investigation by the isolation of actinomyces from these lesions. Further observations of this kind should go far towards resolving the problem.

My thanks are due to Sir Almroth Wright for permission to publish this report, and for much help and encouragement throughout the work; also to Mr. V. Z. Cope for his valuable coöperation in the treatment of many of the cases.

PLAGUE IN SOUTH AFRICA.—Several deaths of natives from plague have occurred in the Orange Free State during March. Bacteriological examinations have confirmed the diagnosis. The infection exists amongst, and is being perpetuated and spread by, wild rodents, and possibly also, it is stated, by small carnivora, such as the muishond and meerkat, the flea being the connecting link with man in the chain of infection.

THE PRODUCTION OF BACTERICIDINS BY MICRO-ORGANISMS.

BY J. W. McLEOD, O.B.E., M.B., CH.B. GLASG.,
LECTURER IN BACTERIOLOGY, LEEDS UNIVERSITY;
AND
P. GOVENLOCK,
TEMPORARY ASSISTANT IN THE PATHOLOGICAL DEPARTMENT, LEEDS UNIVERSITY.

General Work on Problems of Inhibition.

FROM the time that cultural bacteriological methods were first well established observations have accumulated which suggest that bacteria may inhibit their own growth and may favour or inhibit the growth of other bacteria. At the present time it is a commonplace, familiar from experience to most bacteriologists, that *Pfeiffer's* bacillus appears to grow particularly well in the vicinity of a staphylococcal colony, but that in the body it tends to be very rapidly overrun by the pneumococcus. Amongst more specific observations may be mentioned that of Marmorek,[1] showing that a filtrate of a recent culture of a streptococcus in a fluid medium containing serum, &c., will not grow the streptococcus, although it is a satisfactory medium for other bacteria. Other examples are the observations showing that the products of growths of *Bacillus pyocyaneus* and of other micro-organisms have bactericidal effects on *Bacillus anthracis*.[2] And, further, there is the example of the inhibition of bacterial growth on the surface of agar slopes from which the original growth has been washed off (vaccinated media), to which attention has been drawn by French observers.

It is to C. Eijkman,[3] however, that we owe much the most extensive, ingenious, and convincing work on this subject.

The technique finally adopted by this investigator was the preparation of agar discs, obtained by pouring agar on to thick pieces of paper with multiple perforations. These discs were laid on the surface of plate cultures of various bacteria, and the inhibition of growth was observed when those areas of the upper surfaces of the agar discs which overlay the perforations in the paper were inoculated. Complete inhibition occurred after varying periods of incubation, and Eijkman maintained that if the disc were removed and heated after inhibition had been established the capacity of the surface to grow various bacteria, previously inhibited, was restored. His conclusion was that inhibitory substances had diffused into the agar disc from the culture below, and he strengthened this conclusion with various subsidiary experiments. He proceeded to demonstrate the production of such substances by most of the bacteria which he investigated, and showed that in some cases the inhibition was specific, or nearly so, to the bacterium concerned, whereas in others (e.g., *B. coli*) inhibition was exerted to an equal or greater degree on many other bacteria. He specially emphasised, however, that he was not able to demonstrate these substances in fluid cultures (bouillon).

Eijkman's work was rapidly taken up with great enthusiasm by Conradi and Kurpjuweit,[4] who drew some far-reaching conclusions about the control of the bacterial flora of the bowel by the "autotoxins" of *B. coli*. Their conclusions are possibly correct, but unfortunately they supported them by some faulty experimental work which contributed largely to discrediting both their own results and the much better founded ones of Eijkman.

Papers were published immediately afterwards by Manteufel,[5] Oebius,[6] Passini,[7] and Rolly,[8] which were mainly directed to demonstrate the inaccuracy of Conradi and Kurpjuweit's work, but also to some extent that of Eijkman. The four workers mentioned concluded that the only satisfactorily proved causes of arrest of growth in cultures were exhaustion of the medium and production of thermo-stable inhibitory products.

Rolly, however, made a number of interesting observations on the bacterial flora of the lower portion of a dog's bowel after cutting it across. No matter how many and what bacteria were introduced they were rapidly dominated by *B. coli*, although *B. pyocyaneus*, staphylococci, or *B. proteus* could grow more rapidly than *B. coli* in sterilised bowel content. Although he does not accept Conradi and Kurpjuweit's hypothesis this phenomenon was puzzling to Rolly, especially since *B. coli* did not multiply in the mouth, where sufficient material suitable for its nutrition was constantly present.

Acid Concentration in Arrest of Bacterial Growth.

For some years after this very little attention appears to have been given to this subject, but two separate lines of investigation bearing more or less directly on the inhibition of bacterial growth have recently been followed.

In the first place the arrest of bacterial growth, owing to *accumulation of acid in culture media containing* fermentable carbohydrate, has been extensively studied, especially in America, by Avery and Cullen,[9] Brown,[10] Lord and Nye,[11] and others. *Without going into detail with regard to this* line of investigation it may be said that attention is specially drawn to the importance of acid concentration in terminating the growth of bacteria in cultures. Another point, however, bearing more closely on our subject emerges from the work of Lord and Nye. These investigators point out that at H. ion concentrations half way between the optimum for growth, pH 7·8, and the acid death point, pH 5, there is a marked tendency for pneumococci to undergo autolysis. This effect the authors attribute to an intracellular enzyme, which has its maximum activity about pH 6·5. They are inclined to think that this enzyme may be an important factor in the crisis in pneumonia and in resolution of the fibrinous exudate.

"Bacteriophage," Theory of d'Herelle.

The other line of investigation is that which has centred round what has come to be known as the "phénomène de d'Herelle," although as a matter of fact somewhat similar observations had been published by Twort [12] a short time before. D'Herelle's original observation,[13] published in 1917, was that if one or two drops of the fluid stool from a case of bacillary dysentery due to a Shiga infection were added to 20 c.cm. of bouillon which was incubated overnight and then filtered through a Chamberland filter it was found that even quite small quantities of this filtrate would rapidly, in from 2 to 12 hours, cause complete clearing of a turbid suspension of Shiga bacilli in bouillon or other fluid, subculture showing that clearing had been associated with death of the bacilli. Further, the cleared bacterial suspension or "bacteriolysat" was then found to have the same properties as the original filtrate—i.e., a trace of it added to a fresh emulsion of Shiga bacilli would again cause clearing of the suspension. The phenomenon could be repeated indefinitely. D'Herelle's explanation was that the cause of the clearing was an ultramicroscopic virus which had the peculiar property of living on Shiga bacilli and which he proposed to call a "microbe filtrante bacteriophage." In a series of publications which rapidly followed d'Herelle proceeded to extend his observations, till finally he has reached the conclusions that most bacterial diseases are associated with an intestinal "bacteriophage"; that resistance to the disease is dependent on the activity of the latter, and even that the persistence of the infection, "carrier state," can be ascertained by demonstrating the persistence of the "bacteriophage" in the intestinal contents. D'Herelle has been supported in his conclusions by Wollmann,[14], Bablet,[15] and Salimbeni.[16]

Alternative Theories.

Dumas[17] and Debre and Hagenau,[18] however, bring forward a number of observations on the phenomenon which it is difficult to bring into line with d'Herelle's explanation. Such are that, whatever other bacterium a filtrate attacks, it will always attack emulsions of Shiga bacilli; that a lysed tube will after a long time again become turbid from bacterial growth, and yet if tested on a fresh emulsion it will still show the property of promoting lysis; that filtrates with properties similar to those of d'Herelle can be obtained from bouillon incubated with material from very varied sources (Seine water, *stools of normal individuals, soil, &c.*), such filtrates being active against *B. coli* and *B. Shiga*, but never against the cholera vibrio.

Kabeshima,[19] after working for some time with material obtained from d'Herelle, and demonstrating that the "bacteriolysats" might be capable of therapeutic application, definitely challenges d'Herelle's explanation of the phenomenon, and advances a number of reasons for considering that the bacteriolytic property observed is due to a ferment. His chief arguments are that the active principle resists destruction by heating up to about 75° C., and that it can be precipitated by acetone. He considers that a ferment derived from the bacilli, a "pro-diastase," is brought into play by a special "*ferment d'immunité bacteriolysant*" derived from the bowel of the infected animal. D'Herelle disputes most of Kabeshima's experimental results, but admits that the "bacteriophage" can withstand heating for one hour at 65° C.

Lastly, Bordet and Cuica[20] have made an experimental study of the phenomenon, and have shown that *after* repeated injections of *B. coli* into a guinea-pig's peritoneum the peritoneal exudate withdrawn has exactly the same property of clearing an emulsion of *B. coli* that d'Herelle recognised in his original filtrates for Shiga emulsions. They show further that the *B. coli* which can be cultivated on agar with some difficulty from these lysed emulsions differs from ordinary strains in several respects, and especially in the power to initiate lysis in bouillon cultures of coli. This property is retained even after repeated subculture. Bordet and Cuica reject d'Herelle's explanation and maintain that certain ferments of the body probably derived from the leucocytes impart to the *B. coli* an increased tendency to autolysis, and that this is hereditarily transmitted. They maintain, however, that it is a highly specific property, being exerted only on the same microorganisms.

It is unfortunate that neither d'Herelle nor any of the investigators cited have examined this phenomenon in the light of the older observations of Eijkman. Although the lines of investigation are too diverse to allow of a close comparison, it seems quite likely that all the data accumulated may be explained on the simpler hypothesis of Eijkman—e.g., Dumas's observation that filtrates from cultures of earth, river water, and normal fæces tend to lyse emulsions of *B. coli* and *B. Shiga*, but not cholera, may be very simply explained by the presence of *B. coli* in all three of these materials, Eijkman having demonstrated that *B. coli* cultures diffuse substances destructive of dysentery and coli bacilli, but not of cholera vibrios.

Personal Work.

Our own work on this subject will be most readily discussed in two parts: firstly, a number of observations made by one of us without knowledge of the literature reviewed above; and secondly, observations made with a modification of Eijkman's technique.

Earlier Observations.

These were carried out at intervals from the autumn of 1917 onwards, the first object being to prepare a medium unsuitable for growth of *B. coli* but permitting dysentery bacilli to multiply. It was thought that *B. coli* might differ from dysentery bacilli in the nitrogenous elements required for its nutrition, and that it would therefore be possible to exhaust a medium by growth of *B. coli* without using up all the nitrogenous material suitable for the growth of dysentery bacilli. After a few unsuccessful preliminary experiments had been made with ordinary media, recourse was had to tryptic media. In the course of investigating those it was observed that many intestinal bacteria, pathogenic or not, grow well in a 1/5th dilution of Allen and Hanburys' commercial trypsin (cholera was an exception); but that the filtrates obtained from such cultures after a few days' incubation were unsuitable for the growth of the microorganism originally cultivated. The phenomenon was to a certain extent specific; thus the filtrate of a Shiga culture grew *B. coli* or a Y dysentery strain but not Shiga, whereas the filtrate of a "Y" culture grew *B. coli* and Shiga, but not "Y" dysentery. Unfortunately, with *B. coli* the specificity broke down; when the filtrate failed to grow *B. coli* it would not grow any of the dysentery strains. Any of these filtrates, however, when diluted 1 part in 5 parts water, again became suitable media for the growth of any of the bacteria. There was obviously, therefore, no exhaustion of the medium, but apparently some inhibitory factor was at play. The growing qualities of these filtrates, however, were not improved by boiling (this result is at variance with other observations made by different methods described later). As the investigation had broken down in its main purpose, that of obtaining a medium for facilitating the isolation of the dysentery bacilli from the stools, and as a medium containing an "unknown quantity," such as commercial trypsin, was unsuitable for investigating the exact nature of the inhibitory phenomenon this line of inquiry was dropped. As the suggested production by bacteria of substances inhibitory to their own growth raised the interesting, although remote, possibility of the eventual therapeutic application of such substances, further evidence for their existence was sought in cultures of such bacteria as tend to die off rather rapidly. Streptococci and pneumococci were chosen for further investigation.

The results with streptococci, although favouring the idea that production of inhibitory bodies rather than exhaustion of the medium was responsible for the arrest of growth, were not striking. With pneumococci, however, more definite phenomena were observed. The most important of these was that when repeated subcultures were made on serum agar from serum bouillon cultures of certain strains of pneumococci the culture appeared to die off and revive repeatedly, and that after the first 48 hours the growths on subculture to serum agar often consisted of very small stunted colonies, as if some inhibitory substance had been carried over to the plate from the serum bouillon and was preventing the colonies from reaching their full development. The complete scheme of such an experiment is given in Table I., for four different strains of pneumococcus.

TABLE I.—*Results of Plating from Fluid Culture on to Serum Agar Plates.*

+ = Colonies too numerous to be easily counted. ++ = Profuse growth. − = No growth. Numbers = numbers of colonies developing. Bn. and h.s. = Bouillon and horse serum. + (f.) = Numerous but very small colonies. + (f.c.) = Mixture of very fine unusually large colonies. Contd. = Contaminated.

Strain A was one which usually grew readily in bouillon even when lightly inoculated, and it was least liable to die off. The other three strains rarely grew in bouillon unless heavily inoculated, and not always then. They grew pretty constantly, however, in serum bouillon even when lightly inoculated. The phenomenon of repeated revival is best seen with strain C. The intermittent negative results on subculture presumably mean that the bacterium, although still alive in the culture, is present in such small numbers that no living cocci are taken in a loopful, or only such as are so heavily laden with inhibitory substance that they fail to develop.

Determinations of reaction on various tubes in which growth persisted or had been arrested showed that those in which growth persisted were often more acid than those in which it had ceased. As a rule, the reaction of the medium had altered from pH 7·6–7·8 at the outset to about pH 6·9 (colorimetric determinations by Clark and Lubs's technique[21]). The explanation of the phenomena recorded, either by exhaustion of the medium or by development of excess of acid, is not easy; but the supposition that an unstable bactericidal substance was developed which often disintegrated before the bacteria had been completely killed off would fit the facts.

Observations with a Modification of Eijkman's Technique.

The modification was to substitute for Eijkman's perforated paper agar discs, a plate poured in two layers: a melted tube of agar was inoculated and poured and after it had solidified hot agar (80°-90° C.) was run on to the surface so that a thin layer of sterile agar was superimposed on the deep culture. The inhibition of growth on the upper surface was then observed after varied periods of incubation.

Applying this method of observation to the four strains of pneumococcus already mentioned in Table I. it was found (Table II.) that strain A, although sensitive to inhibition by the other strains, was a weak producer of inhibitory substance.

The figures in the last four columns indicate growth observed on surface 18 hours after inoculations on surface.

* Indicates late appearance of a few colonies—i.e., 3 days after surface inoculation. Col. = Colonies.

Strain B, which most of all tended to die off in culture, was also sensitive to the inhibitory bodies, but in addition produced them actively. Strain C produced a moderate amount of inhibitory substance, but was not particularly sensitive to it. Strain D was not particularly sensitive to the inhibitory substance but tended to produce it powerfully and for a longer period than the other strains. Inhibition appeared to reach its maximum usually about the third day and to decrease on the fourth, owing probably to death or weakening of the deep culture and gradual dissipation of the labile inhibitory substance generated. Although the diffusion of inhibitory substances from the bacteria into the agar could be very reasonably inferred from these experiments direct proof was lacking. It seemed to us that conclusive evidence would be obtained if the inhibitory effect could be demonstrated in medium completely separated from the bacteria and that effect then removed by heating. Such conclusive proof was not brought forward in Eijkman's experiments as we understand them.

It was proposed to cut out a sterile disc of agar from the upper layer of a plate showing inhibition and inoculate one-half untreated and the other after heating. The technical difficulties in this investigation were considerable; serum agar deteriorates as a medium for growing pneumococcus after heating, so this bacterium was unsuitable; with the more coarsely growing bacilli such as *B. coli* cutting out of sterile discs is very difficult unless the second layer of agar is deep, and in that case it is not easy to charge it sufficiently with inhibitory substance. A solution, however, was found in the unexpected discovery that the pneumococcus inhibits not only its own growth but also, and to an even greater degree, that of many of the more coarsely growing bacteria. Thus staphylococcus, *B. coli*, Flexner's dysentery bacillus, and *Streptococcus fæcalis* were all inhibited on the upper surface, when the deep plate was inoculated with pneumococcus, and incubation had proceeded for 24 hours or more. These bacteria were found to be sensitive in varying degrees, staphylococcus most and *Streptococcus fæcalis* least.

The results of inoculation on sterile portions of agar, heated and unheated, cut out from the surface of deep plates of various pneumococcal strains are given in Table III.

Pn. = Pneumococcus. + = Abundant growth.
++ = Very abundant growth.

In addition to destruction by heat the inhibitory effect for various bacteria produced on a plate surface by deep growths of pneumococcus was often observed to disappear spontaneously about the fifth or sixth day of incubation, or, if the plates were left for some days, at room temperature. The rapidity of death of the cultures of pneumococcus on serum agar varied according to the type of peptone used to prepare the agar, and it was in the media in which the pnemococcus died most rapidly that spontaneous disappearance of inhibitory effect on the surface of the medium was most readily observed.

Observations on Inhibition by Other Bacteria.

In a general way most of Eijkman's observations, which had dealt mainly with the coarsely growing bacteria, were confirmed by the technique described above. Table IV. shows the inhibitions of growth which were observed.

* As only one strain of some of the bacilli were examined, these results will probably be altered to some extent by extended observations. The results refer to observations made after 24-48 hours incubation.

† The deep plate was serum agar in this case; but the results as above, with a hæmolytic streptococcus were not modified when serum agar was substituted for ordinary agar.

Sh. = Shiga. Fl. = Flexner. P.B. = Paratyphoid "B." St. = Staphylococcus. C. = *B. coli.* T. = Typhoid. S.F. = *Streptococcus fæcalis.* Pn. = Pneumococcus. Mn. = Meningococcus. S.H. = *Streptococcus hæmolyticus.* Y. = Dysentery "Y." Ch. = Cholera.

The data are incomplete; they depend for many of the bacteria on a small number of experiments; and the factors involved in inhibition probably differ—e.g., we have some evidence that the heat resistance of the inhibitory substance produced by the pneumococcus is greater than that of the substances responsible for inhibition produced by *B. coli* and Shiga. In a general way, however, the bacteria amongst those examined most capable of inhibiting others appear to be pneumococcus, paratyphoid B, and *B. coli;* those least inhibitory to others to be cholera and staphylococcus; those most specific in their inhibition hæmolytic streptococci, K.L.B., and typhoid; lastly, those least sensitive to the inhibitory influences are *B. coli* and paratyphoid B.

Production of Inhibitory Substances in Fluid Media.

Advance in the study of, or possible utilisation of, the inhibitory substances would both be difficult if, as in Eijkman's experience, they could only be demonstrated in solid media. Working with serum bouillon cultures of pneumococcus, however, this is not the case. In a few experiments which have been made it has not been possible to demonstrate inhibition of the growth of staphylococci, &c., in cultures of pneumococci made in test-tubes; but when the culture is incubated as a thin layer of fluid in the bottom of an Erlenmeyer flask the inhibitory substances appear. Although a relatively heavy inoculation of staphylococcus is made to a 24-hours' culture of pneumococcus which has been incubated as described no staphylococcus can be detected on plating out after further incubation over night, and the filtrate of the culture has the same bactericidal quality. This bactericidal effect was partly removed by heating at 80° C. for 35 minutes and completely removed by heating at 85° C. for the same time.

The inhibitory or bactericidal effect for staphylococcus and other bacteria was demonstrated equally in a culture which had turned acid (pH. 6·8) and in one in which the reaction had remained unchanged (pH. 7·9), and was in both cases removed by heating to 85° C.

Summary and Conclusions.

A considerable amount of general evidence has been brought forward to show that in the course of reproduction many bacteria produce substances inhibitory of their own growth and of that of other bacteria. In the case of the pneumococcus we believe that we have obtained conclusive evidence that such substances are produced and that they are relatively labile bodies destroyed by heat at 80°–85°C. A free supply of oxygen seems to be important for their production, and it seems possible that it is in this fact that we have the explanation of the therapeutic value of oxygen administration in pneumonia. The possible applications of these findings are various. They have considerable theoretical interest, in the sense that a class of substances, perhaps of the nature of enzyme, which has not as yet been seriously investigated, is brought under examination. Further, it may be possible in taking those substances into account to elucidate some pathological and bacteriological problems till now obscure, such as the crisis in pneumonia or the predominance of certain types of bacteria in different parts of the alimentary tract.

Amongst the likely practical applications are a better understanding of the factors dealt with in preserving stock cultures and in obtaining growths of "delicate" bacteria; also the production of media capable of promoting selective bacterial growth—e.g., it may be possible to prepare a medium capable of growing cholera and not *B. coli*, &c. Lastly, it is remotely possible that such substances may have a therapeutic application, since it may be that the pneumococcal product which kills staphylococci and pneumococci and leaves streptococci much less affected may be more lethal to the former than it is to the tissues of the body.

In any case some very interesting lines of investigation are opened out, and it is in the hope that other bacteriologists may be led to take them up that these observations have been published in this immature form.

In conclusion, we wish to thank Professor M. J. Stewart for facilitating the prosecution of investigations in his department; also Dr. A. G. Ritchie and Mr. R. E. Bevan-Brown, M.A., for help with some of the earlier experiments. We are specially indebted to Dr. G. A. Wyon for modifications of technique in the adjustment and determination of reaction in culture media which he has introduced into the department,* as these have greatly contributed to the accuracy of *much of the work recorded in this paper.*

OBSERVATIONS ON THE
MOBILE ASCENDING COLON.

BY E. R. FLINT, F.R.C.S. ENG.,

SURGICAL TUTOR, GENERAL INFIRMARY, LEEDS.

A GREAT deal has been said and written of late years about the undue mobility of the ascending colon and its consequences, the standard of mobility being derived from the description of the colon given in the text-books on anatomy. I have recently pointed out[1] the fallacy of utilising dead-body dissections as material on which to base conceptions of the living tissues. The shrivelled, fixed structures found in a preserved body have about as much resemblance to the flexible, movable living tissues as an Egyptian mummy has to a man in the full vigour of life. This applies with much point to the ascending colon, for it is described and figured in anatomical books as lying squat on the posterior abdominal muscles and kidney with no suspicion of a mesentery, whereas this sessile state is quite the exception in the living body. I make this statement with confidence after observing the condition of the ascending colon in many hundreds of cases both at operation and in the post-mortem room. It is rare not to be able to lift the colon up into the wound with ease.

What exactly constitutes an abnormal amount of mobility is difficult to decide, though those cases where the colon, and especially the *hepatic flexure*, can be brought out on to the towels can certainly be said to be a less common form of mobility and, therefore, possibly an abnormal type. All degrees of mobility exist, from a complete mesentery to the whole ascending colon and cæcum to a complete fixation throughout the entire length; sometimes the upper end is free and the lower fixed, sometimes just the reverse, and again both ends may be more or less fixed and the centre part mobile, but undoubtedly the commonest type is some considerable degree of mobility throughout, lessening towards the hepatic flexure.

I do not agree with those who hold that it is a matter of prime importance that the ascending colon should be devoid of a mesentery in order that it may raise its load against gravity or that it receives its support normally from its peritoneal attachments. Good tone in the abdominal muscles is, I think, quite an effective support, and these muscles, pressing the liver back against the colon, can bring a considerable steadying effect to bear on the hepatic flexure. Indeed, it seems to me to be a distinct advantage to a muscular organ not to be tethered. Surely if it were so vital that the ascending colon should be fixed in order that it might perform its function properly, nature would have provided a definite point d'appui, as she has done at the splenic flexure in the phreno-colic ligament.

---

* In this work Dr. Wyon was able to check colorimetric observations with a Wendts' electro-titration apparatus obtained under a grant made by the Medical Research Council.

[1] Brit. Med. Jour., Jan. 22nd, 1921.

Another point to which I wish to refer is the very frequent presence of a strong peritoneal band attached on the one hand to the colon in the neighbourhood of the external longitudinal muscular band at a point where the cæcum and ascending colon unite, and on the other spreading out into and becoming a part of the parietal peritoneum on the postero-lateral wall of the abdomen at the level of the iliac crest. This band, which I do not find described in any publication, is very commonly present, and becomes tight on moving the colon inwards and downwards. To my mind it suggests that the tendency of the cæcum, when the ascending colon is normally or abnormally loose, is to move not downwards directly, but in the arc of a circle of which the ileo-colic vessels are the radius, and this band is to prevent too free a migration in this direction. That some such restraint is necessary in certain cases seems probable in the presence of an ileal band. This anchors a short segment of the ileum, about 1½ to 2 inches from the cæcum, to the pelvic brim; if now the cæcum should move downwards and inwards across the true pelvis a sharp kink must occur at this point. This might cause a certain amount of delay in the passage of the ileal contents, but there is no evidence of actual obstruction.

Waugh[2] contends that gastric and duodenal ulcers and gall-stones have all a common underlying cause in the dragging effect of the loaded cæcum and ascending colon on the respective organs, and he figures peritoneal lines of stress in support of his contention. I have been unable to verify these observations. I grant that it is easy to produce these lines of stress in the peritoneum if the colon be lifted or pulled out of the abdominal wound, but with the organs remaining in the peritoneal cavity I find it is impossible to exert traction on the stomach and first part of the duodenum or gall-bladder. Occasionally the second part of the duodenum appears to be dragged upon to some extent; however, ulcer is very rare indeed in this part; also, it would appear possible to obtain some dragging effect on the kidney. Moreover, the cæcum does not drag directly downwards as I pointed out above, but tends to pass towards the left, and any drag which might occur would be expended on the peritoneum to the outer side of the colon; this I believe does occur, and is countered by the band to which I have already alluded.

Again, it is very rare to find the cæcum in the true pelvis; it is kept out by coils of small intestine, the rectum, the bladder, and in the female by the uterus and its appendages in addition. The bladder alone must occupy a considerable part of the pelvic cavity during the 24 hours, as it is more often partially filled than empty, and one fails to see how a bulky organ like the cæcum (bulky because it always contains gas and frequently fæcal matter) could frequently obtain entrance to this confined space. There seems to be no opportunity, therefore, for a heavy drag downwards, when the parts are within the abdomen.

It might be said that X rays show an excursion of the hepatic flexure from below the liver to as low as the iliac crest. That is so; but in these cases there is usually a general tendency for all the organs to prolapse to some extent owing to a lack of support from the abdominal muscles, and the movement is forwards as well as downwards. Moreover, X ray appearances are apt to be deceptive sometimes, for I have seen cases which show an apparent prolapse of the hepatic flexure on the screen, and at operation this part of the colon has been quite reasonably fixed. After all, X rays only show the shadow and not the real organ.

These remarks have been made in reference to the ascending colon, but the anatomical inaccuracies as regards fixity apply to the descending colon as well. It is said that it is exceedingly rare to find a mesentery here, whereas I have found it to be 1 to 1½ inches in length almost without exception; the most fixed parts being the splenic flexure and where the descending colon joins the sigmoid.

Relation of Dyspepsia to Mobility of the Colon.

There is no doubt that certain dyspeptics have very mobile proximal colons, but this does not necessarily mean that the dyspepsia is caused by the mobility; for exactly the same symptoms are found with less degrees of mobility, and even with an ascending colon which is fixed. This last type is sometimes represented by a sharp backward bend, just proximal to the hepatic flexure, showing two parallel limbs adherent to one another, and often also with a strong tethering band from the omentum passing across to the lateral abdominal wall. There is nearly always associated with this a full, soggy, loose cæcum, which occasionally may be turned right up in front of the ascending colon, and very frequently there are calcified tuberculous mesenteric glands in the ileo-colic angle, and an ileal band. There is no question of drag in these cases on other abdominal viscera.

It is rare to find evidence of muscular hypertrophy in the ascending colon, cæcum, or small intestine in so-called loose colon cases. If these structures were trying to lift a load against gravity under unusual difficulties, as is held by some, one would expect to find hypertrophy in some degree. The inference is that, for some reason, there is disordered muscular power in this class of dyspeptics—an arrhythmia, so to speak. Keith's observations point to a defect in the structure of the neuro-muscular tissues, which is distributed more profusely in some situations than in others; it is particularly plentiful in the ileo-cæcal sphincter and in the distal half of the colon, and, to a lesser extent, in the ascending colon, especially where it joins the cæcum. He considers there is a definite sphincteric tract here. His view is, that at these parts there is a hypertonicity (possibly a hyperplasia of this Auerbach's tissue), and that the majority of intestinal stasis cases arise from this cause and not from atony. Fibrosis of Auerbach's tissue is a later stage. There must be some agent which starts this hyperplasia, and the detection of this agent is, to my mind, the real problem in these cases, as, indeed, it is in nearly all chronic diseases; for in such hyperplasia followed by fibrosis is the usual sequence of events. At present we know nothing of these early origins; indeed, there is scarcely a single chronic disease of which it can be said that we know it from A to Z with such certainty that there is no conceivable fallacy in any link in the chain. And this is especially true of large intestine disorders, for we do not know with any accuracy even the normal function of this segment of the gut. But we can, at any rate, by observation arrive at an average mobility which will represent within wide limits the normal anatomical state. It seems to me essential that this point should be cleared up in order that treatment may be based on a sure footing.

Operative Methods.

In dealing with dyspeptic cases associated with a mobile proximal colon the two chief operative methods employed are colopexy and colectomy, partial or complete. If it is true that this part of the intestine is normally freely mobile, then it is hardly conceivable that the indigestion is due to this state of affairs, and colopexy can only be the proper treatment in certain cases—namely, where the freedom of movement is so great that it is possible to get some degree of volvulus, and, I believe, in those cases with an ileal band and so movable a cæcum that kinking may occur at this point. If the symptoms are due to changes in the neuro-muscular tissue of the colon and ileo-cæcal region, and progressing to destruction of it by fibrosis, colectomy becomes the rational treatment at this stage. However, both these operations seem to me to be attempts to deal with the ultimate or penultimate results of some condition, which I think physiologists, biochemists, and experimentalists are most likely to discover—a discovery which, I believe, would be attended by revolutionary effects in respect of many more diseases than intestinal stasis.

---

[2] British Journal of Surgery, January, 1920.

Whether colopexy or partial colectomy should be performed depends on the post-operative morbidity. The mortality is negligible in either case. I have not had a single death. Unfortunately, the post-operative results are not very satisfactory. The patients may gain weight and feel better, but they have to continue taking aperients as before, and too often continue to have flatulence, capricious appetite, occasional hæmatemesis, are lethargic and far from normal. In other words, the real source of the symptoms does not seem to have been touched. Excellent results do occur, and, I think, more often after colectomy than colopexy, because the former operation being performed for those cases which show a soggy, heavy, opaque-looking cæcum, from which it is clear, however it originated, the patient is now being chronically poisoned, an obvious source of danger is removed. The type of case in which the treatment is not so simple shows no such "cesspool," but a mobile proximal colon, while to all external appearance its structure is normal. In these, I believe, neither colopexy nor colectomy is required, except when the cæcum is so loose that it may become rotated on itself, or when there is an ileal band and the mobility of the cæcum is such as to allow of a kink occurring at this point. I think some cases of so-called appendicular colic are really colicky attacks due to some such partial twisting of the cæcum. Colopexy is preferable to dividing the band, for it has a tendency to reform.

It is interesting to note what happens after complete colectomy. I have only done three cases, and all of them returned to a state of marked constipation. Occasionally an inveterate diarrhœa results, but I think the usual experience is to see a return to constipation. This would seem to indicate that it is not the large intestine which is primarily at fault. Moreover, this is an operation which can only be required (if at all) in the more advanced types of stasis, and these are just the patients who are not the good operative risks which so extensive an operation requires. If surgeons would observe and record the state of mobility of the colon in all their abdominal cases we should soon get at the average condition for the living patient and be independent of the text-books on anatomy, which I hold are incorrect in this instance as in some others. I make a para-umbilical incision in adults in practically every abdominal case, except for gall-stones and pelvic operations, displacing the rectus outwards; this gives a perfect scar, as no nerves are divided, and through it one is able to examine the colon attachments quite easily, and, I might add, determine the state of all the other abdominal viscera.

Summary.

1. The colon has a considerable degree of mobility. 2. There is frequently a band present, which prevents undue movement of the cæcum across the true pelvis. 3. The statement that a mobile proximal colon exerts a drag on the other viscera requires further evidence before it can be accepted. 4. It is not proved that the mobility of the colon accounts for the formation of ulcers, or even for dyspeptic symptoms; the same symptoms occur when the colon is fixed. 5. Colopexy is indicated for certain cases; and the symptoms in such cases may simulate appendicular colic. 6. Colectomy is indicated when the cæcum is obviously acting as a "cesspool" and the results of hemi-colectomy are as good as, and the risks much less than, those of complete colectomy.

SOCIETY OF M.O.H.: NAVAL, MILITARY, AND AIR FORCE HYGIENE GROUP.—A meeting of this group will be held at the Royal Army Medical College, Grosvenor-road, London, S.W., on Friday, May 6th, at 4 P.M. Lieutenant-Colonel P. S. Lelean, C.B., Professor of Hygiene, will give a demonstration of "Sanitary Appliances of Interest to all Health Officers." The demonstration is open to all members of the Society.

AN EXPERIMENTAL INVESTIGATION INTO THE ACTION OF CERTAIN ELECTRICAL TREATMENTS ON THE BLOOD, BLOOD PRESSURE, AND METABOLISM.

BY W. BAIN, M.D. DURH., F.R.C.P. LOND.,
W. EDGECOMBE, M.D., M.R.C.P. LOND., F.R.C.S. ENG.,
W. SHIRLEY KIDD, M.B., B.S. LOND., M.R.C.S., L.R.C.P. LOND.,
AND
SINCLAIR MILLER, D.S.O., M.C., M.B., B.CH. BELF.

THIS investigation was undertaken to determine the effect, if any, of certain electrical procedures in common use at the Royal Baths, Harrogate, on the blood, blood pressure, and metabolism; the last as evidenced by changes in the urinary output and in the body-weight. The subjects of the experiment were three normal individuals—A, B, and C, of ages 64, 49, and 35 respectively. Each remained on a fixed and weighed diet, which differed somewhat in detail in each case but was constant throughout for each individual. The blood was taken at the same hour each day (12.30 P.M.) and estimation made of the hæmoglobin, red cells, and leucocytes. The blood pressure, systolic and diastolic, was taken by the auditory method before and after each treatment. The urine was collected daily in 24-hour periods, and the following estimations were made: Total quantity in cubic centimetres; total solids in grammes as calculated from Long's coefficient; total acidity expressed in grammes of HCl.; ammonia nitrogen in grammes by Folin's method; total nitrogen in grammes by Kjeldahl's method; total urea in grammes by the hypobromite method; phosphates by the uranium nitrate method, using cochineal as an indicator; and uric acid by the Folin-Schaffer method.[1] The subjects entered upon a preliminary period of fixed diet for six days, during the last three of which, when equilibrium was presumably established, the urine was collected and estimation begun. The following procedures were then investigated.

(1) *The d'Arsonval high-frequency current.*—This has been used largely for some years as a reputed means of reducing high blood tension, chiefly of the nervous type, and also in hyperpiesis and arterio-sclerosis. Auto-condensation is the method usually employed. In the form of bipolar "massage" it is given locally as a counter-irritant in chronic joint affections; as the "effleuve" it is used largely in cases of chronic neuritis, and by general application to the limbs and body as a tonic and stimulating agent. Each subject had daily for *four consecutive days ten minutes' auto-condensation* with a current of 500 milliampères, followed by 20 minutes' bipolar "massage" to the bare skin of the back and limbs with a current of 250 milliampères. After a rest period of three days—

(2) *The diathermic current* was given daily for 20 minutes on three successive days to all three subjects. It is chiefly used locally to joints and other parts to relieve pain—e.g., in neuritis, fibrositis, periostitis; to promote the absorption of chronic inflammatory thickening; and in local conditions of defective circulation, chilblains, erythromelalgia, intermittent claudication, &c. On the first day it was given locally to the gluteal region, a current of 1 to 1·5 amps. being used; on the two subsequent days the current was passed through the body from hand to foot, the maximum amount tolerated being given in order to ascertain if any general effects were produced. After a rest period of two days—

(3) *The Bergonié treatment* was given. This has a reputation in the reduction of obesity and is largely used for that purpose. A current, interrupted at regular intervals, is passed through the body from a

* Figures between parentheses are the average of six days, 13–14 to 18–19.

large electrode placed on the back, to two electrodes bound on the thighs above the knee. Rhythmical contractions are set up of the large masses of muscles in the back, gluteal regions, abdominal walls, and thighs; and the work done is increased by placing weights on the abdomen and thighs. In the original form no heat is employed. A useful modification has been introduced at Harrogate of an electric light bath given simultaneously, whereby free sweating is induced. A needle bath graduated from warm to cool terminates the proceeding. The treatment was taken by each subject for 20 minutes on six successive days. On the first three days the current alone was given; in the last three days the sweating bath was added. The current used was 12 to 20 milliampères with a rhythm of 72 per minute; and the weights applied amounted to 68 lb. The temperature of the light bath was 125° to 130° F., and the subsequent needle douche was begun at 98° and cooled down to 75°.

Summary of Results.

The results are set forth in the tables appended. In order to save space, the averages only are given of the daily figures for the periods before, during, and after each series of treatments. A brief summary is as follows:—

1. *High-frequency Current.*

Pulse-rate.—Uniformly reduced at each sitting in all three subjects; the average reduction varying from four to eight beats per minute. No net reduction in pulse-rate at the end of four days. This effect is not entirely due to the influence of rest. For example, subject B had a period of 40 minutes' rest before each treatment, and though starting each time with a low pulse-rate of 60 a reduction took place on each occasion to 56.

Blood pressure.—A reduction in systolic pressure, up to 20 mm. Hg, occurred after each sitting in two of the three subjects; the diastolic pressure showed little or no change. In the remaining subject (B) the systolic pressure was uniformly low (100–104) and no immediate reduction occurred. All three subjects showed a net fall of from 4 to 15 mm. Hg. in systolic pressure after four days' treatment; and in the cases of A and C a reduction in diastolic pressure of 8 and 10 mm. respectively. In B the diastolic pressure remained unchanged. The average immediate reduction in systolic pressure of all three subjects at all four sittings was 5 to 8 mm., while the diastolic pressure showed no change.

Blood.—In all subjects there was a slight reduction in the amount of hæmoglobin, while the red corpuscles remained practically stationary. Recovery in hæmoglobin value rapidly took place during the ensuing rest period of three days. The number of leucocytes fell in two subjects, A and B, and the fall endured throughout the subsequent rest period. In subject C a slight rise took place, probably owing to the fact that he was out of sorts, suffering from a pronounced cold.

Urine.—The only changes in the urine common to all three subjects were a diminution in total solids of 8 to 12 per cent., and an increase in the output of urea of 3 to 9 per cent. The other constituents showed little change in two of the three cases. In subject C there was a notable fall in the average excretion of uric acid, but as he was definitely abnormal at the time this finding is neglected as aberrant. During the succeeding interval of three days the average leucocyte count remained down in all subjects; the total solids of the urine rose and the output of the total nitrogen rose above its former average level.

The net results, therefore, obtained from the d'Arsonval high-frequency current were a slight but definite reduction in systolic and diastolic blood pressures; a temporary trifling loss of hæmoglobin; a more enduring fall of leucocytes; an increase in output of urea, followed by an increase in the excretion of total nitrogen. The clinical claims made that this form of electrical treatment reduces the blood pressure and stimulates metabolism are substantiated to a moderate extent by these results.

2. *Diathermic Current.*

Pulse-rate.—The average rate showed practically no change.

Blood pressure.—A fall in the average readings of systolic blood pressure occurred in all three subjects, the maximum average fall being 7 mm. Hg. The greatest individual fall after a sitting was 22 mm. Hg. The diastolic pressure in one subject (B) showed an average fall of 5 mm.; in the others no change took place.

Blood.—All subjects showed a slight fall in the average number of red cells, and in two out of the three a marked increase in leucocytes was observed. In the third subject (C) the average of counts showed a slight fall, accounted for by a considerable drop on the last day after a preliminary rise on the first two days.

Urine.—The changes common to all were a marked increase in ammonia nitrogen amounting to 75 per cent. in two cases and 25 per cent. in the subject C. The total nitrogen was diminished in two cases, and practically unchanged in subject B. The urea was definitely increased in all three; the uric acid showed a distinct increase in two cases, and a minute fall in subject B.

During the succeeding interval of two days a fall in the leucocyte count took place, the red cells remaining unchanged. No variations common to all were observed in the urinary output.

TABLE II.—*Averages of Blood Examinations in Subjects A, B, C.*

—	Hæmoglobin %.			Red corpuscles.			Leucocytes.		
	A.	B.	C.	A.	B.	C.	A.	B.	C.
Before (4 days) ...	101·5	101·2	104·8	5,480,000	5,438,000	6,625,000	8,820	11,010	6400
d'Arsonval (4 days)	99·5	101	102·8	5,420,000	5,500,000	6,425,000	7,410	10,912	7225
Interval (3 days)	100·7	100·3	104·3	5,413,000	5,450,000	6,333,000	6,183	8,660	6660
Diathermy (3 days)	100·7	101	104	5,358,000	5,383,000	6,300,000	7,300	10,600	6283
Interval (2 days)	101·5	101	103·5	5,308,000	5,400,000	6,325,000	6,100	10,200	5700
Bergonié (3 days)	102·3	102·7	105·3	5,407,000	5,400,000	6,396,000	7,017	10,730	4983
Bergonié, with heat (3 days) ...	98·7	97·7	100·7	5,288,000	5,375,000	6,343,000	8,917	9,400	5760
Interval (2 days)	101·5	100	102	5,367,000	5,387,000	6,225,000	10,425	10,400	5950

The diathermic current may be said, then, to cause a slight fall in systolic blood pressure, an increase in leucocytes, and an increase in urea and ammonia nitrogen. These changes are very similar to those produced by the d'Arsonval current, which is to be expected, seeing that both procedures are forms of high-frequency currents. The only notable difference is in the behaviour of the leucocytes—diminished by the d'Arsonval, increased by the diathermic current. In view of the local heat-producing effects of the latter this is an interesting fact which tends to substantiate its clinical use in promoting the absorption of local inflammatory products.

3. *Bergonié Treatment: First Three Days without Heat.*

Pulse-rate.—An average fall of three to eight beats in all three subjects.

Blood pressure.—A definite rise in systolic pressure was observed in all three subjects, the maximum individual rise at a sitting being 24 mm. Hg. The average rise after three sittings was 12 mm. Hg in subjects A and C, who had normal pressures. Curiously enough, in subject B, who had a subnormal systolic pressure, the maximum rise was only 4 mm., and the average rise of three sittings worked out at only 1 mm. Hg. The diastolic pressure showed an average rise of 5 mm. in A and C, but no change in subject B.

Blood.—In all three subjects a slight rise in hæmoglobin occurred, the red cell count being practically unaltered. The leucocytes showed no constant change, a slight rise occurring in two subjects (A and B), and a slight fall in subject C.

Urine.—In estimating the effects on the urinary output we have excluded the findings in subject A for the reason that he was able to take very little current and was markedly upset during the treatment. The only effects common to B and C were a diminution in the output of uric acid; the urea and total nitrogen showed no notable change.

Second three days with heat superadded: Pulse-rate.—In all subjects a rise in pulse-rate up to 30 beats per minute took place during the heat and electricity, followed by a fall after the needle bath, but not to the original level before the bath; the pulse in each case remained on the average a few beats quicker.

Blood pressure.—The systolic and diastolic blood pressures fell in each case during the heat, but not to the extent that would be expected had heat been employed alone without the electric current. The current alone without the heat causes, as shown above, a rise in pressure; when both are used simultaneously the lowering effect of the heat overbalances the raising effect of the current, and the net result is a moderate fall, averaging about 7 mm. systolic and 10 mm. diastolic in the three subjects. With heat alone a much greater fall would be expected. After the needle douche a marked rise in both pressures, averaging 12 mm. systolic and 6 mm. diastolic took place in all three subjects. It is noteworthy that subject B, having a subnormal pressure, showed smaller changes in pressure than A and C, but a much wider variation in pulse-rate.

Blood.—The blood changes showed a marked fall in hæmoglobin in all three subjects, ranging from 4 to 5 per cent., a slight diminution in red cells appeared, and a rise in the leucocyte count in two subjects, A and C, and a slight fall in subject B.

Urine.—Neglecting the result from subject A for the reasons given above, the changes common to B and C were an increase in total solids; a slight fall in the ammonia nitrogen; a marked fall in the output of urea; a rise in the uric acid, marked in the case of B, slight in C, and a slight increase in phosphates. Comparing the averages of the six Bergonié days, three without heat and three with heat, with the averages of the preceding rest period, the total solids are up in both subjects, the ammonia nitrogen up in B and down in C; the urea is down in both; and the uric acid slightly down in both, a fall in the first three days being followed by a rise in the second three; while the net result in the output of phosphates is a slight increase. During the subsequent rest period a fall in total solids, ammonia nitrogen, total nitrogen, urea, and uric acid were common to both.

Summing up the effects of the Bergonié treatment, the current without heat causes a slight rise in hæmoglobin value; when heat is added a marked fall takes place. The blood pressure is *markedly* raised by the current alone to an extent which suggests caution in the employment of this form of treatment in subjects of obesity with a high blood pressure. The addition of heat neutralises the rise and converts it into a slight fall, a fact which favours the employment of heat in addition to the current in these cases. Conversely in cases requiring sweating baths, in whom a fall in blood pressure is undesirable, this effect of heat may be prevented by the simultaneous use of the rhythmical current.

Judged by the urine analyses the Bergonié current appears to have a definite effect in increasing metabolic

TABLE III.—*Averages of Blood Pressures in Subjects A, B, C.*

changes, though not to the extent, at any rate in these experiments, that might a priori have been expected.

Weight.—During the whole period of the experiment all three subjects lost weight. Subject A lost 5 lb. 8 oz.; subject B, 1 lb. 10 oz.; C, 2 lb. 8 oz. During the period covered by the Bergonié treatment subject A lost 2 lb., B 8 oz. only, while subject C gained 2 lb. 8 oz. In these experiments, therefore, no constant result was obtained in the anticipated reduction of weight. On a previous occasion, some years ago, subject A had 26 sittings of 40 minutes' duration on consecutive days; no loss of weight resulted from the treatment.

DELAYED MANIFESTATIONS OF SYPHILIS,

INCLUDING THE REPORT OF A CASE OF LUETIC DUODENAL ULCER.

BY HAROLD SPENCE, B.A., M.D.

IT is not easy to determine in what measure the gloomy prognostications which quickly succeeded the enthusiasm following the introduction of salvarsan have been fulfilled. Within the space of a few years not merely the treatment but the diagnosis and study of syphilis were put on quite a different plane by the discovery of the *Spirochæta pallida*, its demonstration in various tissues, and the development of serological methods.

Yet few who were actively engaged in special practice a decade ago are in any doubt that we are witnessing a real increase in recurrent, or latent, syphilis: and a peculiarly disquieting feature is the frequence of recurrence in primary sero-negative cases given short intensive treatment to serological "cure."

Are we justified in regarding serological and actual cure as parallel, in basing an assumption of sterilisation upon the nature of a reaction which at the moment we can only describe as an accidental physico-chemical phenomenon? Does the period before the blood W.R. becomes positive offer with vigorous treatment the prospect of rapid sterilisation?

General adenopathy and the recovery of spirochætes from the inguinal lymph nodes coincidently with the development of a primary sore alone suggest that at this early period an infection can hardly be regarded as a local affair, and as long ago as 1912 Wechselmann[1] reported definite involvement of the central nervous system indicated by pleocytosis and increased solids in the spinal fluid in six patients with primary syphilis, an observation that has been frequently corroborated since. That the incidence of early spinal involvement is by no means low is shown by the figures of Wile and Hasley,[2] who, after excluding those cases showing only an increase of one or two cells over an arbitrary normal of eight, found definite implication in 49 out of 221 consecutive cases of primary and frequently sero-negative syphilis.

The experimental studies of Brown and Pearce,[3] however, carry us a long step forward, indicating that after successful inoculation the *Spirochæta pallida* very quickly gains access to the blood- and lymph-vessels and is widely planted throughout the body. In a considerable series of experiments they found by systematic determination of the presence of spirochætes in the lymph nodes and circulating blood of infected rabbits that the virus was generally distributed within 24 hours after exposure, or long before an initial lesion could be detected. It is not always safe to apply too literally to the human host data the result of animal experimentation, but in this instance clinical experience and laboratory investigation both point to a close similarity in behaviour and to the wide deposition of the virus in man a considerable time before the blood Wassermann becomes positive—a circumstance of obvious importance when deciding adequate treatment.

In reviewing the results and computing the value of more recent methods one is led inevitably to a comparison with the unique experience of the late Sir Jonathan Hutchinson.[4] His routine treatment with mercury and chalk in small dosage over a considerable period is well known, and in an active professional life of over fifty years he secured, as he well says, "a kind of experience (of lues) that falls to the lot of but few." Of late results among his own patients he saw "exceedingly little" and of the more serious affections of the nervous system "nothing." On the contrary: "I have seen many of those who in their early adult vigour I had treated for syphilis, now in honoured grey hairs and apt to boast of their grandchildren." Specific neurotropic disorders present a fascinating study, but in this paper I desire to report some recent cases of no less interest and importance, but involving other tissues.

Some Recent Cases.

Dermotropic reminders by virtue of their situation *sub oculo* and well-defined characteristics are readily recognised, the asymmetry of later manifestations, their frequently orbicular or circinate shape, distinctive colour, tendency to dry scaling or in moist parts to ulceration, the rapidity of their development relatively to lupus vulgaris, and the very typical combination of papules, ulcers, and scars in one group, leaving little possibility of error; but the existence or nature of a visceral condition may become apparent only at a relatively advanced stage or when irreparable mischief has been wrought. Disturbed action of the heart is attributable to many causes, not necessarily organic, and it is usual and eminently proper to go through the list of these before investigating the possibility of a luetic pericarditis. Similarly, there may be a long period of anæmia and ill-health, coupled with periodical attacks of digestive disturbance, before melæna or a frank hæmorrhage leads to a careful review of the history, followed by clinical, serological, and röntgenological investigation, the elective action of antiluetic remedies finally and definitely incriminating syphilis.

CASE A.—The patient, aged 31, complained of frequently recurring colds in the head and a relaxed throat, which prolonged treatment as for sinusitis had failed to relieve. There was a nasal discharge of ropy purulent secretion which stained his handkerchief. Examination confirmed accessory sinusitis, and there was also found a squamous syphilide on the scrotum and a moist lesion near the anus. Syphilis had been acquired in France a few months previously, for which he had received in the primary stage the War Office course. Wassermann test ++. Relief rapidly followed treatment with an arsenical preparation, mercury, and iodide of potassium.

With strange unanimity, and often in perfectly good faith, patients give a negative reply when asked if they have spots anywhere on their bodies, but the habit of examining every patient thoroughly is sometimes rewarded by a valuable clue to the possible ætiology of an obscure complaint. Apart from evidence of congenital taint in the patient or his offspring, or the more obvious sequelæ of the acquired disease, there may be found, *inter alia*, a periosteal node, suggestive anæmia, hypertrophied papillæ or a dry "bald batch" on the tongue, an enlarged testicle, dystrophied nails, or a peculiar bluish tinge often imparted to mucous membranes or to the skin of the scrotum. A point worthy of note and in some way attributable to the newer methods of treatment is the appearance of lesions ordnarily classed as late secondary, tertiary, or parasyphilitic comparatively early in the course of the disease.

Syphilis of the Alimentary Tract.

It is frequently said that syphilis has a predilection for the extremities of the alimentary tube, but in practice nothing is so often missed as syphilis of the rectum, unless it be cancer.

CASE B.—The patient, a young man, acquired syphilis in March, 1919, and received in the primary stage the usual military course. He was told, and believed, he was well, but seems to have subsequently had rather frequent sore-throats and his voice was inclined to be husky. For some weeks he had been receiving medical treatment for hæmorrhoids and at length had been promised operative relief. Examination revealed pruritus, a small internal pile, the presence of pus, and a lesion detected by the examining finger within the anus on the anterior wall. Through the proctoscope was seen a gummatous ulcer in this situation with some more superficial ulceration adjacent. Wassermann test +. Under mixed treatment rapid improvement ensued.

Autopsy findings indicate that syphilis, inherited or acquired, may attack any part of the alimentary system, eliciting the usual small round-cell response and leading eventually to connective-tissue overgrowth, granulomatous changes, or ulceration peculiar to itself or closely simulating malignant or tuberculous conditions. The necropsy figures of Chiari,[5] who found in 243 pathologically demonstrable cases of lues (145 hereditary and 98 acquired) only 2 involving the stomach and intestines, have been widely quoted as showing the infrequency of gastro-intestinal syphilis, criteria accepted as denoting unquestionable syphilis being tertiary ulceration, gummata, and definite scarring. Flexner,[6] reviewing the literature in 1898, was able to collect only 14 authentic gastro-intestinal cases, and alludes to the difficulties in assessing damage attributable to an organism then unknown. Osler and Taylor both thought the incidence of syphilis of the alimentary canal apart from its extremities as low and in their respective works dismiss the subject in 12 and six lines. Serological investigation, the advent of the Rontgen ray, and in a more definite way the microscopical study of appropriately stained tissues and demonstration of the spirochæte therein made possible by the researches of Noguchi, Levaditi and Marie, Hauptmann, Warthin, and others, had amplified our knowledge of the less obvious activities of the specific micro-organism, and syphilis is being incriminated in a rapidly lengthening list of affections of the viscera and serous membranes, and particularly in those of which infiltration and fibrosis with concomitant changes is a feature. More instances of luetic involvement of the gastro-intestinal tract have been reported in the past five or six years than in five-and-twenty previously, embracing cases of single and multiple gummata originating in the submucous tissue, perivisceral inflammation or diffuse infiltrations of the walls, leading to ulceration, alterations of contour or stenoses.

CASE C.—A male patient, now aged 41, accidentally acquired syphilis in September, 1914, secondaries appearing with a positive Wassermann before treatment was commenced. This consisted of salvarsan 0·45 and 0·6 g. intramuscularly, followed by mercury pills for two months, the blood Wassermann then being negative. Symptoms of gastro-intestinal disturbance were first noticed on Dec. 10th, 1917, when on active service, and consisted of chilliness, moderate pyrexia, epigastric discomfort, eructation, but (as on subsequent occasions) without vomiting. Distress describes more accurately than pain the feeling that would come on at first an hour, and as time progressed three hours, after food, felt over a wide area centred at a spot 1 cm. to the right of the ensiform cartilage and in following attacks referred also to the back. Pyrosis, burning, and gnawing sensations were not prominent, sodium bicarbonate in 30 gr. doses gave relief, and during this and subsequent attacks was taken up to 2 or 3 drachms daily.

The first attack lasted four weeks and those that followed varied in length from two to four weeks and were usually precipitated by definite indiscretions in diet or drink, particularly ale in immoderate amount. Succeeding attacks occurred in June and October, 1918, in March and August, 1919, a short one in February, 1920, being followed by that to be now described. In July, 1920, while entertaining friends to dinner, the patient became suddenly ill, weak, and almost collapsed, then recovering somewhat was taken home. Here a second syncopal attack occurred and he subsequently passed per rectum bright blood estimated at a pint, followed by smaller amounts during the night. When seen the patient had recovered from the immediate effects of the loss of blood, although very pale; cautious examination revealed no thickening or palpable abdominal tumour, and pressure did not appear to be particularly painful.

X ray examination of the patient erect following a bismuth meal revealed marked pyloric spasm, exaggerated gastric peristalsis, and an enlarged stomach, its greater curvature sagging 5 cm. below the iliac crests. In the prone position a depression indicating the presence of an ulcer on the inner surface of the proximal part of the duodenum was seen, the remainder of the duodenum being relatively a little enlarged. Examination of the other abdominal and thoracic viscera was negative.

In view of the very definite history supported by the presence of a thin scar at the site of primary infection and a positive blood Wassermann the implication of lues was suspected, and novarsenobillon 0·2, 0·3, 0·45, 0·6, and 0·6 g. at 2, 2, 4, and 5-day intervals administered, followed by mercury and 4 g. of potassium iodide daily.

Result.—In the eight months that have since elapsed there has been no recurrence of bleeding, nor has blood been found in the stools. The patient, against advice, returned to business on the tenth day after the hæmorrhage and has been regularly at work since without symptoms, although he resumed a generous mixed diet after the first month. X ray examination seven weeks after treatment was commenced showed no trace of the ulcer, the spasm about the pylorus having disappeared, and the stomach practically resumed its normal position. His bodyweight, which was 193 lb. in 1914 and 168 lb. in 1917, is now 187 lb., and he has lost his anæmic appearance.

Comment.

A casual survey of available medical and surgical literature on gastro-duodenal ulceration reveals in the former a wide diversity of theories and in the latter a customary omission of any views as to causation. Whether operation is performed or medical measures relied upon a long period of semi-invalidism is entailed with no certainty of outlook. Hyperchlorhydria did duty through several editions of popular text-books both as symptom and cause, but systematic gastric analyses show its presence in less than 60 per cent. of cases, and since it is found in many intra-abdominal organic complaints it is considered by Moynihan[7] to possess in diagnosis the least value of any symptom. Many believe with Bolton that chronic ulcer follows acute, whether due to the corrosive action of altered gastric secretions, to lowered general or regional immunity, or hæmatogenous infective influences from a focal condition elsewhere. It is frequently attributed to interference with the blood-supply of the involved area by membranous bands or through obliteration of the vessels, to conditions accompanying appendiceal disease or chronic intestinal stasis.

Cases of this sort are infrequently referred to the syphilologist, yet gastro-duodenal ulceration of luetic origin is accepted as a pathological entity and may hold as well the explanation of post-operative jejunal ulceration. Statistics as to frequency are so utterly conflicting as to be little helpful. Thus Smithies, reviewing 1760 cases of gastric disorder associated with demonstrable pathology in the stomach and duodenum, found 2 per cent. to be luetic; Engel says 10 per cent. and Lang and Neumann 20 per cent. of all gastric ulcers occur in syphilitics, whilst Castex affirms that syphilis is the exclusive cause of gastro-intestinal ulceration.

Ivy,[8] experimenting with dogs, exposed the entire mucous membrane of the pyloric antrum to the exterior and found that even after 12 months so exposed it remained healthy. Abrasions rapidly healed and ulceration artificially produced healed in 15 to 20 days with little or no scarring, but more slowly when manipulated. Infection with *Streptococcus viridans*, *Staphylococcus aureus*, and *Streptococcus hæmolyticus* superadded to manipulation had no further influence, but with a pathological membrane where normal gastric juice was not being secreted ulcers tended to become chronic. Durante,[9] by cutting and ligating the splanchnic nerves, has reported the production of chronic ulceration.

There is ground for the belief that in association with an exciting cause a suitable soil is necessary for the production of chronic gastro-intestinal ulceration. Physical, chemical, or bacterio-chemical excitation is a recognised factor in the development of later specific morbid processes elsewhere, familiar examples being the incidence of glossitis in the smoker and the gummatous ulceration due to traumatism from an ill-fitting truss; and from the general trend of evidence and our knowledge of the morphology and pathology of syphilis we will not be far astray in assigning to it a more important rôle in the ætiology of gastro-duodenal ulceration.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

A CASE OF
ACUTE PHLEGMONOUS GASTRITIS.

BY F. W. EURICH, M.D. EDIN.,
PROFESSOR OF FORENSIC MEDICINE, UNIVERSITY OF LEEDS; CONSULTING PATHOLOGIST, BRADFORD ROYAL INFIRMARY;
AND
J. PHILLIPS, F.R.C.S. EDIN.,
HON. SURGEON, BRADFORD ROYAL INFIRMARY.

ACUTE phlegmonous gastritis is a condition sufficiently rare to make the following case worthy of record.

Walter C., aged 50 years, a publican, was seen by one of us (J. P.) in consultation with Dr. E. Newhouse, of Low Moor, on the evening of Feb. 26th, 1921. The history was that he had from time to time attacks of what he called "gastric catarrh." He got up on Feb. 25th feeling seedy, but "made himself clean his bar taps." He was too ill to "wait on" in the late afternoon and went to bed. Vomiting and severe abdominal pain came on in the early hours of the morning and persisted. Dr. Newhouse was called to see him about 8 A.M. on Feb. 26th. He had a good slow pulse, a normal temperature, a non-rigid, non-distended abdomen. The tongue was thickly coated with fur, coloured bright green by the vomited bilious fluid. He had severe pain in the upper abdomen and was vomiting frequently and copiously. A hypodermic injection of morphia was quickly followed by relief from pain and vomiting. Dr. Newhouse saw him again at noon; he had slept and was feeling comfortable. At 5 P.M. he was looking less well and his pulse was quicker, but he was free from vomiting and severe pain. At 8 P.M. the pulse-rate had gone up to 120 and the man looked very ill; one of us (J. P.) was then asked to see him. There was no abdominal rigidity and no localised tenderness, distension, or fever. The question of perforation or of irritant poisoning was discussed and the patient was removed to the Bradford Royal Infirmary. His condition had become desperate when he arrived there and he died about an hour after admission.

Post-mortem examination.—On examining the abdomen nothing was found amiss, save that the stomach wall was injected and that the liver was fatty. No perforation, no peritonitis, and no disease of the bowels. On opening the stomach the most prominent feature was the unusual thickness of its walls, which ranged from ¼–½ in. The whole of the organ, from cardiac orifice to pylorus, was affected; its consistence was doughy, and there was none of the rigidity and contraction so characteristic of leather-bottle stomach. On pulling on the stomach the peritoneum pealed off like epidermis from a blister. The mucosa showed diffuse, bright red areas of injection, irregularly distributed, not limited to any one part of the organ, such as the curvatures, thus differing from the appearances met with in irritant poisoning. And there was this further distinction: that though the mucosa was somewhat thickened it was not thrown into folds; neither rugose nor dry and brittle, but velvety to the touch and succulent. There were no hæmorrhages, abrasions, or ulcers. Not the mucosa only, but the stomach wall throughout was succulent, and on section exuded a milky fluid, which was found on microscopic examination to be thin pus. The appearance was exactly that of the yellow sloughy subcutaneous tissues in an acute cellulitis of the leg. Bacteriological investigation showed the presence in it of large numbers of a short, Gram-positive diplo-streptococcus. Histological examination showed a diffuse but irregular infiltration, with leucocytes of all the coats of the stomach, with degeneration and partial destruction of the glands, the chief cells and accessory cells of the tubules being equally affected. The infection of the stomach appears to have been a diffuse one, for no focus which might have been the starting-point was discovered, nor was any evidence found as to the origin of the infection.

Remarks.

Very few cases of phlegmonous gastritis have been published. In some of these the condition was secondary to typhoid or was part of a general pyæmia. In Kelynack's case it could be traced to septic infection grafted upon an œsophageal stricture. Streptococcal phlegmonous gastritis appears to be extremely rare; among the few recorded cases there are only one or two in which the infiltration affected the whole organ; in some it has been restricted to the cardiac end; in others miliary abscesses have been noted side by side with a more diffuse inflammation and ulceration of the mucosa. Experimental streptococcal infection, whether by oral administration of infected food or by the direct introduction of the germs into the blood stream, has almost invariably produced not a gastritis but a diffuse enteritis —another illustration of the resistance to bacterial infection possessed by the stomach and of the rarity of such cases, unless we join those who believe in the infective origin of gastric ulcers.

The following sentences from Sherren's article in Choyce's Surgery (vol. ii., p. 399) are instructive:—

> "Since the recognition of the disease by P. Borel in 1656 the number of recorded cases is under 100. The condition is more common in men than in women. ...... In 25 per cent. of the cases there is a history of chronic alcoholism. ...... No case of generalised phlegmonous gastritis has recovered. ...... The diagnosis has so far never been made before operation, and when we consider that it has to be made from a perforative lesion of the stomach or duodenum and acute pancreatitis, it is unlikely that it will often be possible. The history of alcoholism, the frequent vomiting, and the profound general disturbance should cause the condition to be suspected."

GANGRENE DUE TO CARBON MONOXIDE POISONING.

BY DR. V. D. THANDAVAROYAN,
RAI BAHADUR; ASSISTANT MEDICAL OFFICER, HIS HIGHNESS THE NIZAM'S GUARANTEED STATE RAILWAYS COMPANY, LTD., SECUNDERABAD, INDIA.

AN article on this subject appeared in THE LANCET of Sept. 27th, 1919. A similar case was under my treatment in the Railway Hospital, Lallaguda, in January, 1920. The history of the case was as follows:—

One of the children of a head constable of the Hyderabad Railway Police was ill. At midnight the father took inside the room a charcoal stove to warm milk for the child. After feeding the child he went to sleep, closing all the doors and windows, and keeping the stove inside. There were six people sleeping in the room—three adults and three children. Two of the adults—i.e., the wife and a servant woman—were the first to get up in the morning. They found themselves weak and giddy, but were able to notice the condition of the other inmates. They found the sick child dead, the other two children semi-conscious, and the head constable unconscious. All were removed to the Railway Hospital. The two children soon recovered completely, but the head constable only regained consciousness 24 hours later.

Areas of hyperæmia appeared, confined entirely to the *left side*. The face, left hand, lower part of chest on left side, and left thigh were thus affected. The hyperæmic areas on the face and chest disappeared after a few days, but raised and anæsthetic areas appeared on the left hand and thigh. Four days later the little finger of the left hand was found to be gangrenous, and the other three fingers and thumb were almost devoid of circulation. At this time the patient was complaining of tingling pains in the toes of the left foot. A fortnight later one half of the little finger, from the middle to the tip, was completely gangrenous, but the other fingers partially recovered.

The gangrene was dry and did not spread, there being a well-marked line of demarcation. The swelling in the hand and thigh improved under treatment. The patient refused amputation.

QUEEN'S UNIVERSITY OF BELFAST.—The Senate of the University has established a new chair of public health, and has appointed Dr. W. J. Wilson as the first professor. Dr. Wilson has held the lectureship in public health in the University for several years, and has discharged his duties in such an efficient manner that his promotion to the new chair was a matter of course. He is distinguished as a teacher in research and as an author. He recently acted as public health officer for Belfast during the illness of the present occupant of that office.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION FOR THE STUDY OF DISEASE IN CHILDREN.

EXHIBITION OF CLINICAL CASES.

A MEETING of this section was held on April 22nd, Dr. F. S. LANGMEAD, the President, being in the chair.

Dr. F. PARKES WEBER contributed the notes of a case of (?) Lupus Pernio.

Mr. C. MAX PAGE showed a case of

Renal Dwarfism.

There was considerable deformity of the legs, for the correction of which the child had been admitted to hospital. The infantilism attracted attention and suggested the diagnosis, but no albuminuria was found. Estimations of renal efficiency by Dr. H. MacLean revealed, however, that the excretory power of the kidneys was very low, and indicated nephritis of the chronic interstitial form. Radiograms showed the characteristic changes near the epiphyseal lines, which have recently been described and demonstrated before the section by Dr. D. H. Paterson.

The PRESIDENT said that the case emphasised the importance of systematic X ray examination and renal efficiency tests before embarking upon operative treatment in a case in which the suspicion of renal infantilism arose, even though there was an absence of albuminuria. With these precautions the diagnosis would cease to be made after death from operation, as had so often been the case.

Mr. G. S. TROWER showed for Dr. H. THURSFIELD a case of

Scleroderma with Myositis.

The scleroderma was distributed in patches and was especially evident on the upper part of the back and neck. Neighbouring muscles were also infiltrated and their contraction and relaxation were considerably interfered with. Flexion of the legs had resulted and movement was greatly hampered. There was hemiatrophy of the tongue. The general health was not seriously affected, and there had been no fever apart from that associated with an attack of tonsillitis. Dr. Thursfield showed for comparison a girl of 17 in whom the disease was less pronounced and the muscles were not affected. There was, however, atrophy of one side of the tongue in this case also. He regarded scleroderma as a disease not only of the skin, but also of many other structures, and suggested a general toxic or infective cause. In his opinion the cases described by the term "dermatomyositis" fell into the same group as scleroderma.

Dr. PARKES WEBER said that the evidence pointed to the probability of scleroderma being an endocrine affection. He thought that scleroderma and dermatomyositis were distinct.—The PRESIDENT said that the cases added to a group of which many examples had been brought before the section within recent years. All had certain features in common, but there were signs peculiar to each. He did not feel able at present confidently to fuse dermatomyositis with scleroderma; in the former disease the patients were acutely ill, febrile, and often died in a comparatively short time.

Dr. W. J. PEARSON showed a case of

Congenital Heart Disease

in a girl, aged 1 year and 9 months, who had been brought for treatment for "bronchitis." The child was somewhat small and looked delicate and its muscles were flabby. There were neither cyanosis nor clubbing. The liver reached one and a half fingers'-breadth below the costal margin and the spleen was palpable. The maximum cardiac impulse was in the fifth space just outside the nipple line. The area of impulse was large and there was a considerable thrust on the third and second left intercostal spaces with a thrill in the second space. A systolic murmur had its maximum in the pulmonary area and inner end of the second left space, and was also clearly heard at the apex. The second sound in the pulmonary area was accentuated. A skiagram revealed considerable enlargement of the heart, with prolongation upwards to the left of the sternum. The diagnosis suggested was patent ductus arteriosus, with a systolic in place of the more characteristic double (water-wheel) murmur.

The PRESIDENT showed a case of

Congenital Heart Disease without Bruit.

The girl, aged 2 years, had been blue and dyspnœic since birth, and clubbing of the fingers and toes was pronounced. The case was clearly one of congenital heart disease, but no bruit was audible. There was slight increase of cardiac dullness to the right. The diagnosis was regarded as being either pulmonary stenosis with complete or almost complete obstruction or transposition of the great vessels. One of these was usually found post mortem when clubbing and cyanosis was unaccompanied by a murmur.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.

Museum Demonstration.

A MEETING of this Society was held on April 15th at the Wellcome Bureau of Scientific Research, Endsleigh-gardens, N.W., with Dr. F. E. FREMANTLE, M.P., the President, in the chair.

A demonstration of the Museum of Tropical Medicine and Hygiene was conducted by Dr. S. H. DAUKES, the curator, who gave an address on the "prophylactic" system which had been adopted in the arrangement of the Museum.

Dr. Daukes said that the Museum was still in an embryonic condition, but that he hoped that those present would see enough to induce them to visit it again when the scheme was nearer completion. It would be freely at the disposal of all who were interested in tropical and preventive medicine, so that it might have a real national value in fulfilment of the aims of the founder, Mr. Henry S. Wellcome. The Museum was devoted to the study of tropical medicine and hygiene, and it was hoped to cover those subjects in such a way as to be of value to the layman as well as to the specialist. There was great need for all who intended to visit tropical countries to have a practical knowledge of how to ward off the dangers incidental to their novel environment.

It had been decided that the Hygiene Section should be the rock upon which the Museum would be founded. This section would occupy the ground floor, and would include town planning, housing conditions, tropical foodstuffs, water-supply, clothing, conservancy, disinfection, ecto-parasites, and disease vectors; there would also be rooms devoted to statistics and research institutes in the tropics. The other floors were given up to a detailed consideration of the various diseases and to certain special branches of work, such as protozoology and entomology. The diseases were grouped ætiologically, not according to the biological position of the causative agent, but according to the mode of transmission. This was essentially a practical arrangement with a special appeal to those engaged in preventive work.

Dr. Daukes observed that the hygienist tended automatically to place communicable diseases in four arbitrary groups: (1) A contact group, which would probably also include certain diseases of inoculation through breach of surface. In this group would be included such diseases as scabies, tinea, syphilis, gonorrhœa, &c. (2) A respiratory group, including diphtheria, measles, influenza, and many other familiar diseases. Many would be included under the term "droplet infections." (3) An intestinal group, chiefly excremental infections, such as dysentery, cholera, typhoid fever, and certain worm diseases. (4) An insect inoculation group, including malaria, sleeping sickness, and many other tropical diseases. Many of these groups were already well represented in the Museum. On the first floor one-half was devoted to the mosquito-borne diseases—malaria, yellow fever, filariasis, and dengue; the other half contained a group of other diseases conveyed by insects, mites, or ticks, including sleeping sickness, relapsing fever, typhus, Rocky Mountain fever, Japanese river fever, plague, and, provisionally, leishmaniasis. On the second floor was the intestinal group, illustrating especially cholera, dysentery, ankylostomiasis, and bilharziasis; next to this the contact group, including many skin diseases and a few diseases, such as leprosy, yaws, and verruga, in which the mode of transmission was not settled. On the top floor was a group of dietetic diseases—scurvy, beri-beri, pellagra, and, provisionally, sprue. The special sections on this floor included protozoology, entomology, animal parasitology, venomous beasts, and helminthology.

The system of grouping presented certain points of interest from a climatic point of view, more especially with regard to the distribution of the various representatives of each group. The tropical specialist was constantly faced by diseases belonging to the insect inoculation group, whilst his colleague in colder climates was very largely occupied with diseases of the respiratory group. The alimentary group was cosmopolitan, but with a special leaning towards the great fly-breeding centres; whilst the contact group was more or less impartial.

Dr. Daukes remarked that the East and West were daily approximating as far as disease was concerned. A world-wide war had reminded them that such diseases as malaria and dysentery were not essentially tropical, and aerial transport seemed to offer special opportunities for altering the distribution of certain diseases. Our ports were constantly in contact with the problem of so-called tropical disease, and the up-to-date hygienist should have a detailed knowledge of the mode of transmission of *all* communicable diseases and not only of those of his own country. A wide general knowledge was the best foundation for success in any special undertaking. Rocky Mountain fever and Japanese river fever apparently had little importance for the European medical man, yet both these diseases were closely linked to typhus—the scourge of Eastern Europe—and the recent work of Wolbach on Rocky Mountain fever and its tick vector might help to solve the difficult question of the relationship of the Rickettsia bodies to typhus. The work of Noguchi on the *Leptospira icteroides* seemed to form a link between yellow fever and the disease spirochætosis icterohæmorrhagica, which caused considerable trouble in our front line in France. This disease could not be neglected in view of the fact that the *L. icterohæmorrhagiæ* is found in a large percentage of our country rats, and, as recently shown by Fullerton, 4 per cent. of London sewer rats. In such circumstances we could not ignore the possibility of conditions arising which might determine an epidemic of this disease. Pellagra was a disease which for a long time was regarded as peculiar to Italy and certain tropical regions. It was now known that indigenous cases might be found in English lunatic asylums and that the disease was by no means uncommon in certain of the temperate regions of the New World. Recent work had shown that it was probably a food deficiency disease, thus establishing relationship with beri-beri and scurvy, two diseases of great importance to our port authorities, Mercantile Marine and Navy.

Dr. Daukes went on to remark that the hygienist devoted his energies to placing barriers between the sick and the healthy—barriers which prevented the infective agent from passing from the one to the other. By such a grouping as he had suggested these barriers were concentrated and mobilised, ready for immediate action. A series of "barrier charts" had recently been brought out by the Bureau which illustrate this system of grouping in considerable detail.

In the past there had been far too great a tendency to divorce preventive from clinical medicine. It was hoped that a museum such as they contemplated would do much to emphasise the essential unity which existed between these two great branches of medical service—a unity which was especially well seen in the tropics, where prevention and cure must ever go hand in hand.

HARVEIAN SOCIETY.

A MEETING of this Society was held on April 14th, Dr. G. DE BEC TURTLE, the President, in the chair.

Mr. DUNCAN FITZWILLIAMS read a paper on

Nævi in Children and their Treatment,

from the consideration of more than 1000 cases which had been under his care.

He dealt with several points in the ætiology of the condition which were not generally recognised, illustrating the different features by numerous diagrams drawn from special cases and also by photographs. He dealt with the treatment of nævi and relative advantages and limitations of treatment by carbon dioxide snow, excision, cautery, and electrolysis. Mr. Fitzwilliams emphasised the advantages of the Paquelin cautery over the electric cautery, and indicated many of the newer special methods of electrolysis. He spoke also of port-wine stains and nævoid marks, discussing their appropriate treatment.

Mr. KENNETH LEES pointed out that the best treatment for nævi of the scalp was excision, otherwise one was apt to get either a patch of baldness or white hair.

Dr. G. A. H. BARTON, referring to the employment of ether as the anæsthetic in such cases, said he had on two occasions seen a burst of flame playing over the patients' mouths. The patients seemed none the worse after this untoward event, possibly because the flame played over a surface which was moist, and therefore did not burn. He considered ether a safe anæsthetic for these operations, apart from those on the head and neck.

Dr. W. J. FRANKISH mentioned a fatal case of hæmorrhage in an old man with a large nævus of the face and tongue. Nothing stopped the oozing, and the patient died after four days.

The PRESIDENT spoke of the correlation of herpes and nævi, and said that nævi did not appear to be congenital.

LIVERPOOL MEDICAL INSTITUTION.

A MEETING of the Pathological Section was held on April 14th, Dr. J. E. GEMMELL, the President, in the chair.

Professor E. E. GLYNN gave a demonstration of

Apparatus for the Mechanical Distribution of the Various Reagents in the Final Wassermann Test.

Professor Glynn stated that one source of error in the Wassermann reaction was inaccurate measurement of the reagents used in the final test. In No. 4 technique of the Medical Research Council 50 Wassermanns necessitated the distribution of 600 ½ c.cm. or ¼ c.cm. doses of various fluids with a pipette or burette—if the drop method was not used. This distribution took a considerable time, and there was often considerable error from fatigue or boredom. He had devised a semi-automatic machine which simultaneously filled 12 Wassermann tubes with ½ c.cm. doses of any reagent; a rack containing 36 tubes was filled in a few seconds. It was impossible to distribute more or less than ½ c.cm. at a time. The error of the machine was tested with distilled water at 15° C. The maximum error was apparently ± 3 per cent., and the average ± 1 per cent.; this was at least half the error obtained with pipettes or burettes when only 12 doses, not 600, were distributed, and more than usual precautions taken in measuring. One reason for the accuracy of the apparatus was the fact that after the expulsion of each dose no drop remained behind on the nozzles. He had also devised a syringe for distributing automatically three ½ c.cm. doses of the diluted serum of the patient. This syringe was accurate and also left no drops. After using a given diluted serum the syringe was washed out twice with saline before taking in the next serum. Salicyl-sulphonic acid, which would detect one part of albumin in 10,000, produced no turbidity with a third washing.

Dr. FRANCIS B. CHAVASSE read a paper on the

Blood Group in Infants and their Mothers.

He stated that a series of experiments upon this subject in the summer of 1919 showed that the blood group is determinable at birth by macroscopic test of the infant blood against stock sera. The incidence of the four blood groups in the newly born was identical with their incidence in adults. The rapid macroscopic test for the blood group gave incidences of the various groups which were identical with the incidences obtained by more complicated methods, and might therefore be regarded as an accurate test (both for adults and infants). The blood group of the infant frequently differed from that of its mother. Twins might differ both from each other and from the mother. The blood group was a characteristic which was Mendelian, at all events in so far as that in its determination each parent has approximately equal influence.

Where by reason of a difference in the blood group a condition which might be termed "maternal threat" to the child arose, the child's blood was invariably agglutinated by the serum of its own mother. But while the agglutinophilic receptors of the infant's corpuscles were thus invariably present at birth and enabled the blood group to be identified, the agglutinins themselves appropriate to the group thus identified were fully developed at birth in about 30 per cent. of cases, so that in cases of "fœtal threat" to the mother the infant's serum agglutinated the blood of the mother (and of the other individuals of the mother's group) in 30 per cent. of such cases only.

There was no obvious relationship between maternal threat and sterility or between fœtal threat and eclampsia and the toxæmias of pregnancy. The fact, however, that agglutination in vitro was invariable in the former case and common in the latter shows that there was no immunity acquired, the protective mechanism in vivo being referable to the fact that dialysis of agglutinins via the placenta was not permitted by the intervening cells, at all events during life.

The incidence of the blood group in women lying-in was identical with the normal adult incidence. There was no relation between the relative blood group of mother and child on the one hand, and the sex of the child on the other. The transfusion of maternal blood into the infant in cases of melæna neonatorum ought not to be performed unless it had been previously demonstrated that both mother and child belonged to the same blood group. If they differed, as they did in one-third of all cases, another donor should be selected.

The apparatus used in these experiments for performing the macroscopic test for the blood group was shown.

MANCHESTER MEDICAL SOCIETY.

A MEETING of this Society was held in the Medical School on April 6th, when Dr. T. A. GOODFELLOW gave his presidential address, entitled

Some Aspects of Preventive Medicine.

After giving a short historical account of the rise and present position of preventive medicine the President referred to the wide field still open for work in this direction, and drew attention to the unsatisfactory position in the country of puerperal mortality, and to the need for increased knowledge in subjects such as infant welfare, health during the "pre-school" period, disorders of the heart and tuberculosis. He emphasised the existing difficulties associated with the supply of pure milk, and briefly discussed some methods of dealing therewith. After pointing out the essential factors in the organisation of modern methods of preventive medicine he urged the establishment of greater facilities for post-graduate study and for research work, emphasising particularly the necessity for a large increase in resident institutional posts. With reference to administrative machinery the President put in a strong plea for the establishment of new local health authorities constituted ad hoc.

BRIGHTON AND SUSSEX MEDICO-CHIRURGICAL SOCIETY.

AT a meeting of this Society, held on April 7th, Dr. WALTER BROADBENT read a paper on

Valvular Disease of the Heart.

He urged the importance of very careful treatment of rheumatism in children with prolonged rest in bed, in order to minimise the damage to the valves. He had used an ice-bag in acute endocarditis with as much benefit as in pericarditis.

Dr. Broadbent continued: Aortic regurgitation was the first valvular disease to be differentiated, Corrigan, in 1832, describing the different physical signs of regurgitation. The presystolic thrill and loud presystolic murmur when there is no mitral stenosis, first described by Austin Flint in 1862, is very common. Thayer found in 74 cases of aortic regurgitation examined post mortem that 33 had had a presystolic murmur during life without any mitral stenosis. When there is aortic stenosis and regurgitation there may be mitral stenosis, but then often there is no presystolic murmur. The diastolic murmur is loudest at the third left costal cartilage, and may be heard there alone. There is usually also an aortic systolic murmur as well, but this only rarely implies any aortic stenosis. Thayer in his 74 post-mortems found only 3 with stenosis and regurgitation. The aortic second sound must be listened for in the carotids. If it is not audible there is much damage to the valves. The amount of regurgitation must be estimated by the degree of collapse of the pulse, and the extent of the dilatation and hypertrophy of the heart. The difference between the systolic and diastolic blood pressures also gives a measure of the amount. The prognosis of syphilitic cases is worse than that of rheumatic, as the coronary arteries are often implicated. Aortic stenosis is rare with regurgitation, but very rare alone. The pulse is small, the heart hypertrophied, there is an aortic systolic murmur, but no second sound in the neck. In regard to treatment, digitalis is to be avoided unless there are symptoms of failure of the mitral valve. For rapidity of the heart Nativelle's digitalin is safer and better than digitalis. Ulcerative endocarditis attacks the aortic valves more often than any other. In subacute cases the onset is very insidious. Weakness, pallor, quickened pulse, slight evening fever may be noted, and enlargement of the spleen, and sometimes clubbing of the fingers. Later minute subcutaneous emboli on the extrêmities may occur; and red cells may be detectible in the urine. In the acute cases there is high hectic fever, and heart murmurs varying from day to day, and frequently cerebral emboli.

Mitral regurgitation should be treated very carefully in children on account of its liability to develop into mitral stenosis. In adults many systolic murmurs are negligible. The cardio-pulmonary murmur, due to movements of air in overlapping lung, and the systolic scratch over the right ventricle marking the position of a white patch of thickened pericardium occasioned by close contact of the heart with the chest wall, caused many men to be rejected as V.D.H. in the war. If in an adult there is a practically normal first sound followed by a systolic murmur, and the apex is not outside the nipple line, there is a little mitral regurgitation, but the man is fit for a full day's work and may live as long as anyone; yet many of these have been converted by the label V.D.H. into cardiac neurasthenics, afraid to do anything, and developing palpitation from sheer nervousness. The work of compensation falls on the right side of the heart; when that begins to give way there is enlargement of the liver and fullness of the jugular veins, so the liver should always be felt. Mitral regurgitation is the most amenable to treatment of all the valvular diseases, and the one that has made the reputation of digitalis.

Mitral stenosis was not differentiated from regurgitation till about 1870 by Gairdner, though in 1827 a Dr. Adams wrote a paper on constriction of the mitral valve. It is much more common in women than in men, the proportion being nearly three to one. Mitral stenosis was divided into three stages indicative of progressive degrees of severity by Sir William Broadbent. The first stage characteristic of moderate stenosis is when there is a presystolic murmur, a short first sound, and a second sound at the apex. In the next stage the second sound at the apex disappears, and the first sound becomes louder and shorter. There is a presystolic murmur, and a short loud first sound only. The aortic second sound has become so weak through the lessened pressure of blood that it cannot be heard as far as the apex. The presystolic murmur often becomes lengthened to fill up the whole diastole and may be divided into two, like a diastolic and presystolic, as the stenosis increases. In the third stage the presystolic murmur disappears, and only the short loud first sound is left with no second sound. There is not strength enough in the heart to maintain a pressure sufficient to cause a murmur in forcing blood through the narrowed mitral orifice. The heart is rapid and often irregular also. As the whole strain of compensation falls on the right ventricle, which is limited in the amount of its hypertrophy by the smallness of the left ventricle, there is early back pressure in the right ventricle and the liver becomes enlarged sooner than in any other form of heart disease.

The following cases were shown:—

Dr. DONALD HALL: A railway guard, aged 45, the subject of Hereditary Optic Atrophy. His only brother, three nephews, and six male cousins were suffering from the same disease.

Dr. WINKELRIED WILLIAMS: Two Cases of Lupus Vulgaris to demonstrate the value of Dr. Adamson's treatment by liq. hydrarg. nitrat. Also a case of Pityriasis Rosea with "herald patch" on left side of thorax.

GLASGOW OBSTETRICAL SOCIETY.

A MEETING of this Society was held in the Faculty Hall on March 16th, Dr. BALFOUR MARSHALL being in the chair, when Dr. ROBERT JARDINE opened the meeting with a dissertation on the

Methods of Altering the Presentation and Positions Before and During Labour.

He said that these operations were most frequently performed in the interests of the child, but were also often applied to facilitate labour and to spare the mother. He advocated examination a few days before labour to determine the position, which was then, as a rule, the same as that assumed during labour, if secondary face cases were excluded. Spontaneous alteration of position was very unusual at that late stage of the pregnancy, although not unknown. A transverse found at such an examination should always be turned by external manipulations into a vertex or breech. In a primipara the external version should always be to a vertex, and this should be practised when a breech is found in a primipara. He had never tried to alter an occipito-posterior position to an occipito-anterior by external manipulations prior to the onset of labour, although this was possible: He made a plea for the more extensive use of abdominal palpation.

In occipito-posterior positions Dr. Jardine did not approve of the rotation of the head by forceps, as he contended that the head was twisted on the neck, while the shoulders were not turned. The treatment he advocated was manual rotation, aided by the external hand pushing the shoulder across, or, if this did not avail, the fingers of the vaginal hand being extended past the head, and, the shoulder having been gripped, rotation accomplished in this way. Rotation completed he felt that it was advisable to apply forceps therewith. Such cases ought not to be allowed to continue too long in labour. If the head was well flexed Milne Murray's straight axis-traction forceps, twice applied, were often satisfactory. In persistent occipito-posterior positions he advised attempt at rotation, trying first to one side then to the other, which failing attempted forceps delivery with the face to the pubis, despite the possibilities of perineal lacerations.

In face presentations it was advisable to leave all mento-anterior positions except in cases where the head was very large, when it was advisable to convert to a vertex, at the same time rotating the occiput anteriorly. In all mento-posterior cases he thought that interference was justified. With a fully dilated os and unruptured membranes it was advisable to flex the head by manipulation per vaginam, and in cases with ruptured membranes manual dilatation of the os and flexion of the head was desirable before the face could become impacted. He advised immediate delivery with forceps after these manœuvres. All these he had found easy to perform except in primary face presentations, in which he considered version the line of treatment to be adopted. Persistent mento-posterior positions could only be delivered as such if the child was very small; attempts could be made to push the head up in these cases and perform flexion, but failing this craniotomy was to be recommended.

The typical parietal presentations of flat pelvis were interesting. The anterior parietal positions he left to mould, and then delivered with axis-traction forceps in Walsher's hanging-leg position. The posterior parietal positions, fortunately the less common, presented a greater difficulty; these could be converted to anterior parietal presentations if got early and before moulding, but were difficult to maintain in the new position. Delivery by forceps immediately on correction, if possible, was the best method of treatment. If the correction could not be maintained he advised version. Transverse presentations with ruptured membranes were treated by, with fully dilated os, performing podalic version; in back anterior cases the lower leg was taken, while in back posterior cases the leg to be taken was the higher one, thus bringing the dorsum anterior for the completion of the delivery. In cases attended by retraction and impaction decapitation was the correct treatment. In cases of breech presentations with extended legs he felt the delay not due to the splint-like action but to the presence of a retraction ring. The hand was to be forced gently past this, a leg swept inwards, and the child delivered by the application of vis a tergo.

Dr. W. D. MACFARLANE gave a communication on

Cæsarean Section as a Method of Treatment in Central Placenta Prævia.

He began with a review of the lines of treatment employed in cases of placenta prævia. Version was the most satisfactory method from the maternal standpoint, but he deplored the attendant fœtal mortality. Cæsarean section had been employed in four of his cases and had been in every way satisfactory. The operation was the usual conservative method, and in each case mother and child were alive and well. This method of treatment had been adopted because in each case the placenta had been situated centrally and because of the expressed desire of the patient's medical attendants for some line of treatment other than the "old ones" with their unsatisfactory results. From his experience of these cases he felt confident that Cæsarean section was the ideal treatment in cases of this type provided the operator was assured that the patient was not infected, that the child was alive, and that the patient's general condition did not contra-indicate abdominal operation. Much of the success of such operations depended on the complete asepsis of the operation, and it was therefore of importance that they should be treated in nursing homes or hospitals with all the advantages of favourable surroundings, just as acute appendicitis and other abdominal emergencies were treated. With these indications and careful technique he felt that Cæsarean section offered the obstetric surgeon a line of treatment which on the counts of both maternal and fœtal mortality would give better results than any of the methods now commonly used.

LONDON DERMATOLOGICAL SOCIETY.

Compulsory Notification for Venereal Disease.

A MEETING was held at St. John's Hospital for Diseases of the Skin on April 19th, Dr. WILLIAM GRIFFITH presiding. A discussion on the Resolution: "That the Society considers some form of compulsory notification for venereal disease cases to be necessary," was opened by Dr. W. KNOWSLEY SIBLEY, who proposed the resolution.

He said that of the three racial poisons, alcohol, tuberculosis, and syphilis, in most countries there is legislation against alcohol and tuberculosis, but there is still room for legislation in regard to syphilis. Syphilis as a contagious disease should be taken seriously. In scarlet fever and diphtheria the infection is of short duration, whereas syphilis, which is not notifiable, may be contagious over a long period. Dr. Sibley spoke of the colonies and foreign countries in which notification of venereal diseases has proved successful, and of the disadvantages of the voluntary clinic system in vogue in this country. He then summarised the report of the Government Royal Commission on the Prevention of Venereal Disease, and of the policy of the two organisations which attempted to achieve this object. Dr. Sibley said that if there were some form of even confidential notification a patient would be told he or she *must* carry out the prescribed medical directions, otherwise he would be liable to serious penalties. The exact method of procedure following upon notification to the medical officer of health would be a subject for consideration when once the principle had been established. If this could be done Dr. Sibley felt that a great step towards both the prevention and eradication of syphilis would be made.

Dr. DENNIS VINRACE, opposing, said that diseases such as scarlet fever and diphtheria were not comparable to syphilis just because of their short duration. The treatment of venereal disease was by far the most important factor to be considered. Prostitutes were the root of the trouble, and until we could get the beds to deal with them effectively, venereal disease was bound to continue. No form of compulsory notification could affect this. Dr. Vinrace dwelt on the importance of education of the future generation, and praised the publications issued by the National Council in this connexion. He spoke also of the difficulty of diagnosis as an argument against notification. If we had compulsory notification, the patient, in his opinion, would not consult a medical man, but would go to a quack or chemist.

Dr. MAURICE G. HANNAY said that Dr. Sibley had not given the results of notification in other countries. He agreed with Dr. Vinrace that the question of diagnosis was sometimes extremely difficult. A case of pityriasis rosea had to his knowledge been diagnosed by four different doctors as syphilis. Then came another important question, how long should we continue treatment in any one case affected with venereal disease? In Dr. E. F. Buzzard's opinion syphilis remains a lifetime. If this is so, it would be a serious thing in the case of compulsory notification.

Dr. J. FORBES said that if a patient knew that he or she had to be notified to the health authorities on account of venereal disease it would only make the case more difficult for the practitioner. The patient would not attend for treatment but would seek another way out.

Dr. CHARLES BANKS said that he would support Dr. Sibley's views if it could be so arranged that the notification of venereal disease should be confidential.

Dr. J. BRINDLEY-JAMES agreed with Dr. Vinrace that no form of compulsory notification should be necessary, provided complete confidence existed between the doctor and patient.

Dr. A. C. REBELLE felt quite sure that compulsory notification of venereal disease would be of no advantage. No compulsory measures existed in India.

The PRESIDENT said that there seemed serious and weighty objections to the compulsory notification of venereal disease. However, the real point was, what would we gain from compulsory notification of venereal disease; would the disease increase or decrease?

Dr. VINRACE and Dr. SIBLEY having summed up, the resolution was put to the meeting and was not carried.

NO. 20 GENERAL HOSPITAL ANNUAL DINNER.—The second annual dinner of officers of this hospital will be held at the Florence Restaurant, Rupert-street, London, W, on Saturday, May 14th, at 7 for 7.30. Officers intending to be present should communicate as soon as possible with Mr. Harold Drinkwater, 7, Cavendish-place, London, W.1.

Reviews and Notices of Books.

DIETETICS OF GASTRO-INTESTINAL DISEASE.

Diätetik der Magen- und Darmkrankheiten. By Professor Dr. I. BOAS. With chapters on Diet before and after Operations on the Stomach and Intestines, by Professor G. KELLING. Leipzig: G. Thieme. 1920. Pp. 216. About 8s.

IN the preface to this volume the author remarks that the dietetics of digestive diseases, owing to the growth of physiological knowledge, now stands upon a basis firm enough to justify a unified description of its method and strategy. The book, in our opinion, justifies the contention. It is, like its fellow volume, behind the times as regards modern methods of diagnosis. Also, the author seems but ill-acquainted with quantitative researches on metabolism since Rübner, and has little or nothing to do with calories. But the young physician of the present day knows, or can easily learn, enough, and something to spare, of such technical aspects. These chapters, cast in lecture form, supply something harder to get—namely, the experience of a lifetime of careful clinical study of diet in diseases of the alimentary canal. We have read the book with pleasure and profit, and commend it. Its diction is easy, direct, and clear. There are few set diets and hardly half a dozen elaborated schemes. In each disease lines are traced which the diet should follow, but the author insists rightly that the actual prescription must be written by the physician, and ought always to show, not what foods must be avoided, but what foods are to be eaten. A formulated diet, from however distinguished a source, is inferior to that prescribed for the individual patient. Many diseases of the stomach and intestine can be cured by diet alone. A sound warning is given, however, against unnecessary dieting. Food restrictions and cures, if prescribed when not needed—for example, in many nervous states—are more dangerous than medicine, of which an overdose gives definite signs. In this respect we surmise that the doctor sometimes gives way too much to the demands of his patients, some of whom clamour as loudly for a diet as others for a vaccine.

In gastritis anacida it is recommended that the pepsin and rennet ferments should always be tested for. If these are absent it is useless to try to stimulate the glands. Hyperacidity is described as not a disease but an over-action, often, though not always, leading to prolonged and periodic disturbances of the alimentary canal. A diet is recommended by Professor Boas which is poor in salt and extractives, rich in vegetable protein, contains much neutral fat of low melting-point, makes little demand upon mastication and leaves the stomach fairly soon. The foods which are said to meet these requirements are milk, eggs, flours, pea-meal, jellies, vegetables, sugars, butter, cream, olive oil, almonds and nuts (powdered), stewed fruits, lemonade, custard, &c. Such food is taken for three months, after which fish and boiled meat is introduced. Piquant foods should be avoided for a long time. It will be noted that sugar and stewed fruits are not excluded from the diet. Professor Boas says that pure sugar is not followed by pain in hyperacidity, although sweet dishes of mixed composition may be. In the treatment of gastric ulcer a graduated fluid diet, based mainly on that of Leube, is preferred. The Lenhartz diet is criticised because rice and minced meat are given too soon and cream and butter not soon enough; also on account of the high price of eggs. The influence of Lenhartz's advocacy of early feeding is nevertheless obvious, for the old plan of weeks of starvation or "nutrient" enemas receives no support. The same dietetic course is required after the surgical treatment of ulcers as after the medical treatment.

Under the heading of gastrocoloptosis a vigorous reply is given to the claims of Rovsing, that operation is desirable. Professor Boas says brilliant results are obtained almost without exception by rest and appropriate food. As an example of the diet the following may be quoted:—

8 A.M.: Fatty chocolate 50 g., in milk; rusk; wheaten bread; butter; 1 egg.

10 A.M.: Milk 100 c.cm. and cream 100 c.cm.; white bread; butter; ham or white cheese.

1.30 P.M.: 150 c.cm. thick light soup with egg in it; vegetables and potatoes; rice pudding; macaroni; meat or fish; compote of fruit; some mealy food; a bottle of malt beer.

4 P.M.: Tea or coffee with milk and cream; rusk; cakes; toast; rolls; butter 30 g.

7 P.M.: Egg food; switched egg, omelette, all prepared with much butter. Fish or cold meat 50 to 100 g.; white cheese with cream; compote of fruit; bottle of beer.

9 to 10 P.M.: Fatty chocolate 50 g.

If there be also habitual constipation the diet is altered by giving olive oil night and morning, coffee at breakfast and tea, with a tablespoonful of milk-sugar, wholemeal bread, fruit at lunch and dinner, with fish or egg, but little or no meat, and cider at the evening meal. Treatment in such cases, if carried out in a sanatorium, is mainly to be looked upon as an education; and a great deal of the doctor's task is to introduce will, order and discipline into the life of the patient. The diet in chronic constipation is founded upon Rübner's tables of the unabsorbed residue of various foods. The use of a modification of the scheme in many severe cases, and in experienced hands, confirms Professor Boas's claim that results usually come in the first days and persist. Full details are given in this interesting section of the book.

The advice upon food in chronic diarrhœa is especially useful. Milk is often ill borne, but sugar-free milk is recommended. The temperature at which it is drunk must not be too hot or too cold. Sugar should be avoided till the stools are normal, and then added only gradually. Jellies, flours, eggs, fish, cream, and butter are good. Next meat and puré of potatoes may be tried. Fermentation dyspepsia should be diagnosed by the excess of starch in the motions, and is usually relieved by leaving that foodstuff out of the diet. In membranous colitis the author strikes a middle way between the "rough" and "bland" diets. He gives olive oil and paraffin, and is adamant about aperients. In acute appendicitis he thinks surgeons do not appreciate the good results of starvation and oil enemas without opium. Operation is recommended directly the acute attack subsides. Since adopting this method he has hardly ever seen perforation or general peritonitis.

The section by Professor Kelling, a Dresden surgeon, on diet before and after operation—short-circuitings, resections, and gall-bladder operations—is carefully thought out. Of particular interest is the discussion on the treatment of indigestion after gastro-enterostomy, different kinds of food being needed according to the cause of discomfort, such as the entrance of bile and pancreatic juice to the stomach or jejunal ulcers. The latter, he is convinced, are brought on by coarse food. He does not think it necessary to operate on all cases of peptic jejunal ulcer, as he has seen healing with careful attention to diet. Fluids are given at first, then plain meat, fish, and bird, with but little salt. Spices or alcohol and tobacco are not allowed.

This little book is valuable both to physicians and surgeons, and will probably have as much success as Professor Boas's well-known larger volume on diseases of the stomach, of which the new (seventh) edition will shortly be reviewed in our columns.

BASAL METABOLIC RATE DETERMINATIONS.

Laboratory Manual of the Technic of Basal Metabolic Rate Determinations. By W. M. BOOTHBY, M.D., and IRENE SANDIFORD, Ph.D. London and Philadelphia: W. B. Saunders Company. 1920. Pp. 117. 24s.

AT a time when the importance of measurements of the basal metabolic rate is beginning to be realised in this country any book which treats fully and simply of the technique employed in these measurements is welcome. Boothby and Sandiford, working at the Mayo Clinic since 1917 on these problems, have elaborated a routine method by means of which they have carried out determinations of the basal metabolic rate in a large number of cases. Essentially their method consists in collecting the expired air of the patient into a gasometer for a given space of time. This air is measured on the gasometer and analysed in duplicate with the Haldane apparatus, from which data, the height and weight of the patient being known, the basal metabolic rate can be calculated. The method of Benedict meets with criticism at their hands, but their objections are of a somewhat theoretical nature, and there are other and more serious practical difficulties in the Benedict apparatus, which are not present in the open circuit type of apparatus, upon which they do not touch. The book deals very fully with the details of technique at every stage of the determination, and is well illustrated. In their section on the description and management of the Haldane apparatus the authors draw freely from Dr. J. S. Haldane's book, "Methods of Air Analysis," but their volume is, in the main, a full and useful description of the method they have worked out and brought to such a high degree of accuracy. It is especially commendable in its insistent demand for accuracy at every stage of the measurements. Clinical calorimetry is a scientific method of precision—to be of any value it must be used scientifically, and must be precise in every detail. This point cannot be emphasised too often. As the authors state in their preface: "This manual has been prepared in the effort to render this valuable diagnostic method available to any well-equipped and scientifically conducted clinical laboratory, and with the hope that the results of indirect calorimetry will not be thrown into general discredit by a neglect of the details requisite for obtaining a true basal metabolic rate." The book is supplied with a number of useful logarithmic and other tables, and contains all the data necessary for the complete calculation of results. An excellent bibliography is given.

INTERNATIONAL LAW.

Le Droit International Public Positif. Par J. DE LOUTER, Professeur de Droit International Public à l'Université d'Utrecht. London: Oxford University Press. Humphrey Milford. 1920. In two volumes. Pp. 1085. £1 2*s.*

Mr. de Louter's work, now printed in French by the Oxford University Press and published under the auspices of the Carnegie Fund, was orignally composed after the Peace Conferences of 1899 and 1907 had been followed by the Declaration of London; it was published in 1910 at The Hague. The production of an edition in French was a proposal made soon afterwards by those responsible for the Carnegie Fund, and re-editing was commenced. The accomplishment of the design was, however, delayed inevitably by the war, and the author, as a neutral onlooker, had the saddening experience of seeing the rules and principles that he was endeavouring to elucidate for the public good constantly ignored, perverted, and trampled upon. To this he alludes only briefly in his preface, for he writes of the law as it existed before 1914, and leaves to others the task of applying it to the events of the years that followed. It may be long before the facts are sufficiently established for this to be done. With regard to one minor branch of Mr. de Louter's subject for example—the treatment of wounded and of prisoners—wide differences of opinion might obtain as to how far and how often the laws of civilised warfare were deliberately or recklessly transgressed. We may congratulate ourselves, however, that mankind now condemns unsparingly indifference shown by enemies towards the wounded of the other side, or by an army towards its own wounded, when we remember how very recent has been the realisation that the wounded even of an enemy have their rights.

Mr. de Louter traces the history of the present attitude of governments and military authorities towards wounded soldiers from the days when they were killed, ill-treated, or abandoned as a matter of course, to the later period when Florence Nightingale and her nurses strove to abate the horrors of the Crimea. It was soon after that that Dunant, a Swiss, published "un Souvenir de Solferino," stimulated sympathy which centred itself at Geneva, and helped to bring about the founding of the Red Cross Society. It was not within the scope of his treatise, or Mr. de Louter might have recorded appreciation of the influence of science and scientific invention in producing results which are not entirely due to the development of humaner instincts in mankind. Medical and surgical science and modern means of transport have rendered possible standards of national and international humanity not dreamt of in the days of Alma and Inkerman, and still unrealisable at the time of the Franco-Prussian War.

Mr. de Louter's treatise is not wholly concerned, of course, with topics relating to war, its prevention, or its prosecution, and the recognition of medical science in the domain of international law in peace is to be traced in his pages, where he refers to the steps recognised as necessary for preventing the spread of disease from one nation to another. The substitution of modern methods of diagnosis and disinfection for long periods of quarantine has done much to prevent international friction, and at the same time has caused satisfactory results to be achieved with greater certainty. Mr. de Louter's easy style, and appreciation of what is essential for the information of his readers, have enabled him to place in their hands a valuable introduction to the study of international law. As a work of reference it would have been rendered more useful by the addition of an index, but it is informing enough to be worthy of the perusal of anyone who desires to acquire knowledge of the subjects dealt with, and to whom the language in which it is written offers no obstacle.

ORGANIC CHEMISTRY.

Laboratory Manual of Organic Chemistry. By H. L. FISHER, Ph.D. London: Chapman and Hall. 1920. Pp. 331. 12*s.* 6*d.*

Dr. Fisher rightly insists that "a book is never a thing by itself; it is always a growth, and many factors and influences from other workers contribute largely in the making of it." The book is the result of many years' laboratory teaching at Columbia University, and the experiments and preparations described are the outcome of that experience. We would recommend its careful perusal to teachers of organic chemistry in this country, for they would gain many valuable suggestions. A strong point is made of inductive reasoning, and the student is directed when and where to record observations. After each experiment a number of questions from the theoretical and practical standpoint are set out. In the latter part of the book organic combustions are dealt with in detail; this section is well worth reading.

Organic Chemistry for Medical, Intermediate Science, and Pharmaceutical Students. By A. KILLEN MACBETH, M.A., D.Sc. London: Longmans, Green and Co. 1920. Pp. 235. 6*s.* 6*d.*

THE subject matter of this book, which is intended for the use of medical and pharmaceutical students, is not dealt with in an exhaustive manner, but is selected in order that the medical student may be able to take full advantage of subsequent courses in biochemistry, whilst the pharmaceutical student will gain a knowledge of the subject sufficient for his future work. The text-book is based on the author's courses of elementary lectures and in these he states that he not infrequently deals with the aromatic compounds after the corresponding aliphatic types have been described. By this system the student can note the similarity of the synthetic methods and can compare and contrast the properties of corresponding compounds of these two main groups as his work proceeds. In the book the orthodox treatment is followed, but the student is referred from the aliphatic to the aromatic type. We notice a few lapses. Dr. Macbeth speaks of diastase as an organism (p. 59), and of maltose as the chief constituent of sugar in malt (p. 161); moreover, this sugar is crystallised from alcohol, and not, as is stated, from water. But, on the whole, the matter is put together concisely and seems fairly free from errors. A useful feature to the student is the series of questions at the end of each chapter.

Laboratory Manual of Organic Chemistry for Medical Students. By MATTHEW STEEL, Ph.D. Second edition. Revised and enlarged. London: Chapman and Hall. 1920. Pp. 284. 9*s.* 6*d.*

THIS manual was originally compiled as a laboratory guide in organic chemistry for the medical students of the Long Island College Hospital, Brooklyn, New York. Recent developments, more particularly in the domain of biological chemistry, necessitate a much broader training in organic chemistry than was formerly required, and the author has endeavoured to meet this requirement without burdening the medical student with a mass of unessential data. The work, as its title implies, is a practical one and does not deal with the theory of the subject; the experiments and preparations are wisely selected, and the working instructions clear and concise. Alternate pages of the volume are left blank, so that the student may record his own observations. The work concludes with an interesting chapter on the colloidal state of matter treated from the experimental standpoint. Dr. Steel is to be congratulated on the production of a useful and well-balanced volume, which, considering the necessarily wide ground it covers, is singularly free from errors.

Text-book of Organic Chemistry. By A. F. HOLLEMAN. Edited by A. T. WALKER, Ph.D., assisted by O. E. MOTT, O.B.E., Ph.D. Fifth English edition, revised. London: Chapman and Hall. 1920. Pp. 642. 18*s.* 6*d.*

THE fact that it has been necessary to bring out five editions of this well-known work in a period of 17 years is evidence of its service in the teaching of organic chemistry. So many of our short text-books of organic chemistry contain far too many isolated facts, and the number of compounds described confuses the beginner. The author has kept the number of unconnected facts within as narrow limits as possible, and has given prominence to the theory underlying the subject. In this edition additional space is allotted to the applications in organic chemistry of the increasingly important physico-chemical methods such as refraction, absorption, and viscosity. The descriptions of a number of technical processes such as the manufacture of alcohol, cane sugar, &c., are included. Dr. Walker and Dr. Mott deserve well for having rendered the original into excellent English. The work is most readable, and though intended primarily for the student it will no doubt be read by many who desire to keep in touch with the advances in modern organic chemistry.

JOURNALS.

Journal of Pathology and Bacteriology, Vol. XXIV., No. 2, pp. 129-240.—The Neural Origin of Certain Sarcomata of the Brain, by J. R. Perdrau (London). Two cases of mixed celled "sarcoma" of the brain are described in which the author finds evidence that they originated in nerve cells and should therefore be classed as neuroblastoma.—P. B. White (Aberdeen) describes and figures an intrathoracic tumour in a honey bee, possibly arising from a nerve, with the structure of a fibroma.—Method of Mounting Flat Pathological and other Specimens in Gelatin, by T. H. G. Shore (London).—The Diagnosis of Syphilis in Malarial Subjects by the Wassermann Reaction, by J. P. Johnson (South Africa). In a series of cases of malarial infection, confirmed microscopically, without clinical signs or history of syphilis, positive Wassermann reactions (original method) were given by 22 per cent., but on retesting after an interval (not clearly described) this was reduced to 7 per cent., which the author finds no difficulty in regarding as cases of latent syphilis. Using Tschernogbouw's, Fleming's, and the Hecht-Fleming technique, the positive results were 6, 27, and 27 per cent. respectively, and 6, 7, and 11 per cent. on retesting. The author holds that a positive reaction should always be confirmed by retesting before a diagnosis of syphilis is made.—On the Preparation of Diphtheria Toxin, by K. G. Dernby and H. David (Stockholm). The best yield is obtained by starting with a reaction of 7·2 to 7·4 and ending with one of 8·0 to 8·3, which should be attained in about eight days.—The Cultivation of the Gonococcus, by C. E. Jenkins (Salford). The optimum temperature is 35°-36° C., and 10 per cent. whole blood agar is a satisfactory medium. The important point is to keep the culture moist by using a medium with a high water content (as little agar as will give a solid medium) and incubating in an atmosphere saturated with water vapour. The same author points out that a very satisfactory decalcifying mixture, preserving histological detail and staining reactions, is HCl 4, glacial acetic acid 3, chloroform 10, water 10, absolute alcohol to 100.—The Mode of Infection of *Schistosomum japonicum*, by Y. Miyagawa and S. Takemoto (Tokyo). By experiments on mice which were cut in serial section and the total number of infecting larvæ enumerated, the authors find that the young worms penetrate the skin into lymphatics and small veins, and then reach the right side of the heart; from here they pass to the lungs, where they may be arrested for a time owing to their large size; thence into the systemic circulation, by which they reach the intestinal wall, penetrate mesenteric veins, and so arrive at their permanent home in the portal veins in the liver.—An Experimental Study of Avian Beri-beri, by G. M. Findlay (Edinburgh). The histological changes in beri-beri in fowls and pigeons are generally similar to those caused by inanition, but they differ in the nuclear degeneration, the chromatolysis in nerve cells, and the retention of lipoid in the adrenal cortex. The content of ox organs in nucleic acid is parallel to their antineuritic efficacy; thus the potencies of liver, brain, heart, and muscle in preventing beri-beri are as 100, 75, 53, 18, and their richness in nucleic acid as 36, 20, 15, and 5. The author suggests that antineuritic vitamin is an essential factor in the synthesis of nucleic acid.—The Production of Coliform Infection in the Urinary Tract of Rabbits, by E. H. Lepper (London). With various organisms of the coli group no evidence of their passage into the urine after intravenous injection could be obtained without signs of kidney damage (proteid, &c., in urine). Complete obstruction of the ureter for as short a period as a quarter of an hour determines a kidney infection.—The Supposed Importance of Vitamins in Promoting Bacterial Growth, by J. W. McLeod and G. A. Wyon (Leeds). The smallest quantity of various substances which would allow the growth of *Staphylococcus aureus* on a simple phosphate agar was determined and compared with the content of the substances in antineuritic vitamin; with a few glaring exceptions the figures are roughly parallel. The authors do not agree that blood promotes bacterial growth on account of its vitamin-content, and point out that amino-acids are favourable chiefly to intestinal bacteria.—A Study of the So-called Parameningococci, by L. Cronstedt (Stockholm). Thirteen strains isolated from the pharynges of contacts of a single case of meningitis fell into several agglutination groups and on further culture changed their reactions. The author doubts the validity of separating a group of parameningococci by agglutination.

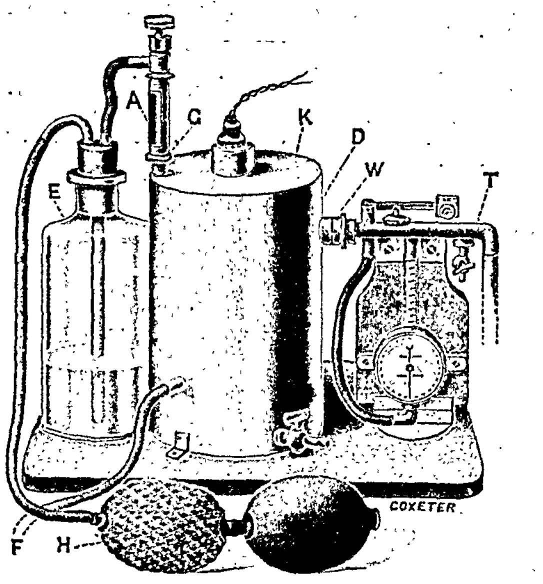
La Médecine (Vol. II., No. 6) for March is given up to diseases of circulation and excretion under the direction of Professor Paul Ribierre. The contributors give good reviews of the present trend of thought and deal with subjects of current interest. The article by P. Ameuille on Acute Nephritis without Nephritis is original in emphasising the view that acute nephritis is not only or at all acute inflammation of the kidneys. The articles by Vaquez on Digitalis, and by Josué on Undeveloped Forms of Cardiac Rheumatism deserve attention. The subjects chosen are highly specialised and dealt with in too cursory a manner to stand by themselves as sources of information.

American Journal of Syphilis. Vol. V., No. 1.—The bulk of the contents of the January number (which by accident has only just reached this country) may be regarded as falling within one of two categories—viz., the specifically technical and scientific, and that which is admittedly clinical. More than half the matter in this issue is devoted to the consideration of subjects which come within the former class. An interesting series of "Studies in the Standardisation of the Wassermann Reaction" include (1) The Influence of Temperature and Duration of Primary Incubation upon the Anticomplimentary Activity of Organ Extracts (Antigens) and Sera; (2) The Influence of Temperature and Duration of Primary Incubation upon the Velocity and Amount of Complement Fixation in Syphilis with Different Organ Extracts (Antigens); (3) A Comparative Study of Methods for Conducting the Primary Incubation for Complement Fixation in Syphilis with the Technic recommended for a Standardised Test. All the foregoing are outside the province of the general practitioner—if he specialises to such an extent his time is overburdened—yet at the same time it is desirable that he should realise the large amount of work which is being carried out in relation to the Wassermann reaction. It is good that he should know of this work, inasmuch as a recognition of its complexities and difficulties may tend to break down the mechanical conception of this reaction, which we fear is still held by many members of the profession, to the exceeding detriment both of their own scientific outlook and their patients' welfare.—Turning to those articles which come within the second category, we regard the paper on the Early Diagnosis of Primary Syphilis, by Dr. C. Guy Lane, as being of great clinical value. It should also inspire its readers with a marked degree of sociological enthusiasm. Many of our readers may be aware that in evidence given before the Royal Commission on Venereal Diseases, 1915, Dr. Douglas White estimated that approximately 10 per cent. of the population in large towns of Great Britain were suffering from syphilis. Dr. Lane informs us that exactly 8 per cent. of the population—i.e., about 8 million persons—in the United States are affected by this disease. This estimate, unlike that of Dr. White's, embraces both the urban and country areas. Such a statement, indeed, affords a sufficient *incentive to the precise and early diagnosis of so devastating* a disorder. We consider that the editors of the journal are acting in the public interest by publishing an article which, with equal lucidity and force, impresses upon practitioners the responsibility which accrues to them in respect to making the earliest diagnosis and initiating the promptest treatment of primary syphilis. Dr. Lane wisely emphasises his statement that "treatment is only as efficient as the follow-up system." We feel that there is an urgent necessity on the part of the practitioner both to assimilate and materialise so pregnant an aphorism. How often is a patient only treated and retained under observation until a negative Wassermann result has been obtained, or until his clinical signs and symptoms have disappeared. We do not suggest that on these findings it is a frequent occurrence for a patient definitely to be told he is cured, but we would emphatically state our belief that the necessity of obtaining re-examination and possibly of further treatment at regular intervals is not sufficiently impressed upon the patients' consciousness. It may be that through lack of knowledge the medical man does not realise the necessity of giving such advice. It may be that a false feeling of sympathy prevents him from hardening his heart and dashing to the ground the hope, which a patient may frequently cherish, that one course of treatment will suffice to cure him. Such a travesty of sympathy is as criminal as it is weak.—Dr. L. J. Owen contributes a suggestive article on Syphilis as an Ætiologic Factor in Nodular Cirrhosis of the Liver. The author reminds us how Adami investigated the evidence bearing upon the production of hepatic cirrhosis by chronic infection, and how he regarded the colon bacillus as being a causal factor in respect to this condition. It is interesting to note to what an increasing extent these once neglected bacilli have been held responsible for the production of morbid conditions. Fox, as the result of some thousands of autopsies on animals, came to the conclusion that alcohol, lead, and syphilis could have no part in bringing about these lesions, and emphasises the importance of infection as a causal factor. The fact that these examinations were carried out on animals other than man robs Fox's conclusions of only a part of their value. Reviewing the work of Dr. Owen it is interesting to note the conclusions he has arrived at as a result of 1200 autopsies performed in the Washington University School of Medicine. From the frequent association of syphilis with Laennec's or nodular hepatic cirrhosis, present in 40 per cent. of 19 cases of nodular cirrhosis, he suggests that the syphilitic virus is a causal factor with regard to the hepatic lesion. He adds that the presence of alcoholism is found to be less than that of syphilis; the incidence of syphilis and alcohol in combination is high, and he suggests that *a combination of the two factors may* produce the disease in question. Thirdly, as regards chronic infective processes—e.g., arthritis and endocarditis, he thinks that, although these have been associated with cirrhosis to such an extent as to justify further investigation, *no definite correlation can yet be established.*—Occupying an intermediate position between the highly technical articles to which we first referred and the two latter clinical ones, there is an attractive and clearly written statement on the subject of Strain in Spirochætes by Dr. Burton Peter Thom. He deduces in a succinct manner some of the data upon which a belief in specific strains of spirochætæ has been advanced. He gives particular attention in this respect to the subject of neuro-syphilis, and concludes that Hutchinson's suggestion as to the possibility of "several variants of syphilis is plausible, but is not capable of proof—at least not yet." He adopts a similar position as to the theory of a life-cycle with regard to *Spirochæta pallida.* Convinced that such a thing as a spirochætal strain does not exist, *he believes that the selective* action of the organism "when introduced into the body is governed entirely by the manner in which the tissues of the host react to the invader."—At the end of the journal there is a full and valuable series of abstracts and book notices, in addition to an index of current literature dealing with syphilis.

New Inventions.

A PORTABLE APPARATUS FOR TRACHEAL INSUFFLATION ANÆSTHESIA.

THE apparatus here illustrated consists of the following parts. (1) Needle valve sight feed (A). This is roughly the size of a 2 c.cm. hypodermic syringe. The lower end is connected by a gas union (G) to a heated air-chamber, and the needle valve to a metal tube passing through a cork to the bottom of the ether bottle (E). The ether reaches the needle valve at a positive pressure maintained by occasional use of the hand bellows (H). In other words, on the principle of a reversed Junker bottle. (2) Heating chamber (D). This part is composed of an outer cylinder (D), 6 inches by 4 inches, and an inner cylinder, 4 inches by 3 inches, the intervening space forming an air-chamber. Air from a Standing's aluminium foot-bellows, or preferably from a compression cylinder, enters the lower end of the air-chamber at (F), passes round the inner cylinder, and leaves the upper end at (W) on its course to the patient along the tube (T). The air-chamber is heated by water, or an electric bulb if available. (3) The safety valve manometer and thermometer are connected with a horizontal tube (T), all mounted as one unit on an upright wooden support. The safety valve is of the simple lever type used on steam engines, and can be easily adjusted in connexion with the manometer to blow off as required. For carrying purposes the gas union screws (G) and (W) are undone, and the safety valve unit and sight feed placed within the heating chamber, which is closed by the lid (K). The apparatus is not claimed to be superior to the more elaborate forms already on the market, but its compactness is a valuable asset in private practice. In hospital practice, where portability is not an essential, and where motor *air pumps are usually available*, a mercurial manometer can be used with advantage in place of the more expensive type illustrated.



The advantages of the apparatus may be summarised as: (1) compactness; (2) abolition of mercury and glass safety valve; (3) portability in an ordinary bag in any position; (4) abolition of the necessity to decant the ether from the bottle to a special container.

The apparatus is made by Messrs Coxeter and Son, 171, Pancras-road, N.W., who have carried out my design in an efficient manner.

I. W. MAGILL, M.B., B.Ch., B.A.O. Belf.,
Anæsthetist to the Queen's Hospital, Sidcup; and Hon. Anæsthetist to the Dreadnought Hospital, Greenwich.

THE LANCET.

LONDON: SATURDAY, APRIL 30, 1921.

The League of Nations and Dangerous Drugs.

THE sequence of events in regard to the enforcement of the Opium Convention of 1912 since the stages described in THE LANCET of May 29th, 1920, and Jan. 15th of this year may be usefully recorded inasmuch as only scattered references to what is going on have found their way into the daily papers. It will be remembered that the first Assembly of the League of Nations, which met at Geneva in December, 1920, resolved that an Advisory Committee should be appointed by the Council of the League with a view to secure the fullest possible coöperation between the various countries concerned and to advise the Council in dealing with any relevant questions which might arise. The Council was further authorised to add to the Committee not more than three persons as assessors, such persons to have "special knowledge of the question" and not to be Governmental representatives. We understand that the Secretary-General of the League accordingly, and under the direction of the Council, invited the following eight countries to appoint one representative apiece on the Advisory Committee—viz., Holland, Great Britain, France, India, Japan, China, Siam, and Portugal. The Council also appointed Sir JOHN JORDAN, Mr. HENRI BRENIER, and Mrs. HAMILTON WRIGHT as the assessors to the Committee. The Committee is charged to submit to the Council by June 1st next a report on "the execution of arrangements with regard to the traffic in opium and other dangerous drugs," which report will be also laid before the next meeting of the Assembly of the League in September.

Meanwhile the draft Home Office Regulations under the Dangerous Drugs Act, 1920, against which were directed so much medical and pharmaceutical criticism, have been the subject of investigation by a Committee appointed with some reluctance by the Home Secretary, and now sitting under the chairmanship of Mr. CHESTER JONES. Any modifications which this Committee may advise in the Draft Regulations are by the terms of reference to have regard "to the main principles on which the Regulations are based and which are essential in the public interest for safeguarding the use of the drugs." The Dangerous Drugs Act, 1920, so far as the United Kingdom is concerned, has given legislative fulfilment to the obligations incurred under the International Opium Convention of 1912, although the essential Regulations to provide administrative effect to this enactment have yet to be promulgated. It will be interesting to learn how many of the 52 countries which are now parties to the Convention have similarly passed the legislation required by its effectuating clauses. The names of the members of the Advisory Committee of the League of Nations have not, we believe, at present been published, and we trust that they may include those having the medical and technical knowledge necessary to enable the Council of the League to avoid some of the difficulties which criticism of the Draft Regulations for the United Kingdom has brought to light here. As regards the assessors and their "special knowledge of the question," we recognise that Sir JOHN JORDAN'S long and honourable diplomatic association with China will be of no little assistance, and that Mr. HENRI BRENIER'S work, both on the Shanghai Commission and the first Hague Conference, was specially valuable; while Mrs. HAMILTON WRIGHT has carried on with indefatigable enthusiasm the labours with which her late husband was identified in restricting the use of dangerous narcotics. Nevertheless, we must express our regret that among the technical assessors to the Committee there is no one specially versed in the medical or scientific aspects of the whole question, for experience has shown that these aspects cannot be disregarded without incurring risks of failure either by way of exclusion or inclusion of important details.

◆

The Work of the Radium Institute.

THE report by Mr. A. E. HAYWARD PINCH of the work of the Radium Institute during 1920 marks a distinct advance upon any of the reports previously issued. The work carried out has grown in volume since its inception; it was perhaps inevitable that in the early stages lines of treatment largely laid down by the French school were followed. But it casts no reflection upon this school to state that radium-therapy as practised in our country to-day follows the dictates of no single body of opinion. The treatment is being shed of its empiricism, and the exact mode of administering radiation to conditions of disease is a matter for careful consideration and discussion. There is a growing tendency towards collaborative effort, so that different minds may be focused upon any single problem. If the surgeon has something to learn from the radiologist, it is no less true that the radiologist has much to gain from getting a surgical view-point of the disease he is treating, and neither will go in vain to the pathologist for information. The present report is presented in a new form. No cases are described in detail; an attempt has been made to present radium therapy in a manner which will guard the science against the reproach of empiricism. A consideration of principles, a review of data obtained from 80,000 treatments, and free reference to work from other sources, have been combined to formulate general laws and give some indications for departure from routine methods in special instances. A total of 8134 treatments were administered during the year, of which 4598 were given free to necessitous patients. 896 cases were seen for the first time, and were classified as follows: Examined but not treated, 78; recent reports not received, 114; received prophylactic irradiation only, 38; apparently cured, 133; cured, 28; improved, 336; not improved, 74; abandoned treatment, 62; died, 33.
The emanation applicators prepared
tributed to hospitals and medical
during the year numbered 765. An
physics of radium therapy is given;
of all apparatus used in treatment
terms of hydrated radium bromide
radium element content of 53·6
is devoted to a brief description
rays (emitted alike by radium
emanation, in a proportion of

of the reflected and emergent secondary rays, of which the latter necessitate careful elimination on account of their irritating effects upon tissue. Clinical experience has led to definite limitation of the thicknesses of the various metals used for screening; the range lies between 0·01 mm. aluminium and 2·0 mm. lead.

Radium rays impart to living tissues a stimulus varying with the character of the rays and the period and extent of their absorption; pathological cells are more susceptible than normal cells, and different varieties of cells react differently to radiation of given wave-lengths. It has been shown that cells are most susceptible when in a state of active nuclear division. The speed and power of α and β rays are gradually reduced in their passage through matter, and finally disappear, but complete absorption of the hardest γ rays never occurs. The action of radium rays on various tissues and organs of the body has been carefully studied by many observers, and a summary of the more important results is given in the report. Thus the changes induced in an area of skin subjected to irradiation are: (1) epidermal proliferation, followed by desquamation; (2) congestion of the dermis, with destruction of hair follicles and sebaceous glands; (3) fibrosis; and (4) regeneration of hair follicles and sebaceous glands. In the blood a rapid increase of red corpuscles has been noted, persisting for some time and associated with a short leucocytosis, followed by a marked leucopenia. Much valuable knowledge has resulted from analysis of the periodic examination of blood of nurses and laboratory workers carried out at the Institute. In these instances the changes in the blood cells are conditioned by repeated short exposures with γ radiation undergone during work. Leucopenia is invariably present; the effect is slowly established, but steady and cumulative, and a prolonged absence from all contact with radium is necessary to restore the leucocytic count—frequently reduced by 50 per cent.—to normal. All who habitually work with radium should be guarded as far as possible against rays which might impinge upon the thoracic and abdominal cavities. The normal thyroid gland is but little affected by radium rays, although arrest of its secretory function, brought about by frequent and prolonged radiations with resultant fibrosis, has been recorded. With reference to the testes and ovaries, the seminiferous tubes and Graafian follicles are extremely susceptible, and degenerate rapidly under radiation. Sterility has been specially observed in unprotected X ray workers, and hard X rays are analogous to the rays of radium.

For specific treatment of diseases certain fundamental principles are enunciated, and it is laid down that the effect of radium irradiation on the living cell shows three clearly established phases: (1) increase of cell activity, with possible associated proliferation; (2) arrest of cell activity; (3) degeneration and destruction of cells. The transition from stimulation to destruction is simply one of degree; no hard-and-fast line can be drawn between the phases. Details of treatment are then discussed under the headings of malignant and non-malignant diseases; the former comprise the carcinomata, sarcomata, rodent ulcers, and endotheliomata, and the latter include fibro-myomata of the uterus, leucocythæmia, exophthalmic goitre, tuberculosis, nævi, keloids, lupus erythematosus, leucoplakia, and warts, keratomata, and papillomata. Superficial skin lesions—chronic eczema, lichenification, and pruritus—are separately treated. The report necessarily contains some theory, but contentious matters have been avoided as far as possible; the whole has been written in the hope of stimulating further inquiry into the problem of radium therapy. The report of the Research Department, by Dr. J. C. MOTTRAM, is appended. Reference is made therein to the publication of a paper dealing with the blood of workers at the Institute,[1] in which are described three deaths of radium workers—two in England and the third in France. In two cases these deaths were ascribed to aplastic pernicious anæmia; in the other the blood condition was similar, but the case was complicated by signs of infective endocarditis. Anæmia of pernicious type was found in several other workers, and it is concluded that exposure to radium was in these cases the important ætiological factor. The increased protection now afforded is already resulting in a return to normal of the blood of these workers. The report of the chemico-physical laboratory, by Mr. W. L. S. ALTON, F.I.C., is also included; the staff of the laboratory is now engaged in problems relating to improvement of methods of measuring the activity of emanation applicators; the difficulty of finding trained assistants has hindered the work somewhat, but it is hoped to publish results next year. Results already obtained are sufficient evidence of the valuable part which laboratory investigations may play in serving the direct needs of the Institute, as well as the larger claims of the subject of radiology.

Insurance Practice and Research.

THE first National Insurance Act clearly recognised in 1911 the need for research in connexion with any new scheme of health administration, and the sum of 1*d.* per insured person was made available for the purposes of research at the discretion of the Insurance Commissioners. The Medical Research Fund Regulations of 1914 defined more exactly how the very considerable revenue from this 1*d.* rate was to be administered, and the fruitful work of the former Medical Research Committee, now the Medical Research Council with a larger scope, is common knowledge to the informed, whether doctors or sufferers. It is doubtful whether imaginative expenditure has ever justified itself so quickly and admittedly by practical results. But the Insurance Act has more than one pocket, and a cache has been revealed in Sheffield as welcome as it was unexpected. There the panel committee, by strict economy and voluntary labour during the war, was able to save £1000, which was invested in War Loan for any acute emergency which might arise. The fact that the Sheffield committee was financed by a voluntary scheme rendered this possible. When the financial situation came to be reviewed at the beginning of this year it was evident that the voluntary levy could be suspended for at least six months, and that the surplus of £1000 could be disposed of. After taking legal opinion the panel practitioners resolved to transfer the War Stock to the University of Sheffield, with a request that it should be earmarked for the equipment of a field research laboratory in the department of pharmacology.

---

[1] Archives of Radiology and Electro-therapy, December, 1920.

This department of the University is organised on novel and sound lines. A whole-time professor of pharmacology has been appointed in the person of Dr. EDWARD MELLANBY, and, in order that the laboratory worker should not be divorced from clinical work, Professor MELLANBY has been also appointed an honorary physician to the Sheffield Royal Infirmary. In so doing the University authorities aimed at breaking down the barrier which now exists between physiological and clinical work, and at compelling the student to think of the patient as a problem in disturbed functions rather than as an item in a heterogeneous catalogue of tabulated symptoms, pigeon-holed under the name of a disease. At the same time the Royal Infirmary Board, thinking that the time had come to obtain for their patients the benefits of expert physiological advice, appointed the University professor of physiology, Dr. J. B. LEATHES, as consultant physiologist to the institution. Further, a joint arrangement with the Royal Hospital and the University has resulted in the appointment, as full-time clinical physiologist to both hospitals, of Dr. C. G. IMRIE, previously deputy professor of biochemistry at Toronto. The department of pharmacology will thus soon be strengthened by the addition of a fully equipped field laboratory for experimental work. Professor MELLANBY will be enabled to continue his work on rickets in relation to fats and vitamins, alongside of which may be recalled Mrs. MELLANBY's striking proof that the problem of dental caries is largely a matter of biochemistry.

There can be no doubt that Sheffield panel practitioners have afforded valuable support to the University of their city in helping along research work which promises to yield fruitful results to therapeutics. Incidentally their generosity cannot fail to create a favourable impression on the part of the general public towards panel practice in the area. A large part of this public consists of insured persons in whose interests the Approved Societies are assumed to act. These societies also have unallotted funds from which contributions might be made to research work. The example of the panel practitioners may prove infectious.

◆

INTERNATIONAL HEALTH PROBLEMS.

THE International Labour Office of the League of Nations has received a request from the League to appoint a delegate to the Temporary Health Committee of the International Health Organisation of the League. It is hoped that this Committee will meet in Paris early next month, the need for it arising from the fact that certain diplomatic measures have to be concluded before the permanent organisation, as decided by the League Assembly, can be set up. It is considered essential, meanwhile, that there should be no delay in carrying out the duties imposed on the League in connexion with international health problems. The Temporary Health Committee will consist of 12 members: a delegate from each of the States permanently represented on the Council of the League (France, Great Britain, Italy, and Japan); a delegate from the League of Red Cross Societies; a delegate of the International Labour Office; the President of the Bureau International d'Hygiène Publique; and five delegates appointed by the committee of that body. This Temporary Committee will cease to exist when the permanent organisation is actually formed.

As will be seen from the leading article upon the action of the League of Nations in connexion with dangerous drugs, the Council of the League is resolved to treat its international responsibilities in respect of health with every importance.

Annotations.

"Ne quid nimis."

THE BASAL METABOLIC RATE AND ITS CLINICAL POSSIBILITIES.

THERE are not wanting signs that in this country the pathological and clinical problems presented by exophthalmic goitre will provide an increasingly attractive field to workers. This is due partly to a wider acceptance of the importance of the rôle of the ductless glands in the bodily economy, partly to the elaboration and more general adoption of surgical technique in the treatment of this disease, and not a little to the introduction to this country of methods of measuring the basal metabolic rate. Out of the discussion lately held at the Royal Society of Medicine on the treatment of exophthalmic goitre, two salient facts have emerged. Firstly, that we are in need of standards by which we can compare the condition of a patient before and after a certain line of treatment, and as a corollary the respective merits of different methods of treatment and the comparative results of individual workers. But this need is met by basal metabolic measurements, which express in figures the severity of a case of Graves's disease at any one time, just as the degree of fever is charted by means of the clinical thermometer. Moreover, as the course of a fever may be followed upon a temperature chart, so the progress of a case of Graves's disease may be followed upon a curve representing the basal metabolic rate taken from time to time. With the assistance of these exact records we may hope that the vexed question of the choice of treatment, which is as much a matter for controversy now as it was ten years ago, will be put at rest. Secondly, that we must look to early diagnosis for further advances. The discussion in point revolved around the treatment of a late and intractable phase of the disease, and it became clear, before the debate had gone very far, that it was not so much to a development of the means at our disposal for dealing with a case at such a stage, but rather to its diagnosis in the early phases of the malady that we should look for real advance. Here also we may receive from metabolic measurements valuable help in recognising an early case of Graves's disease before gross bodily changes have occurred, and while treatment is still effectual. There is a natural reluctance to replace clinical observation by laboratory methods, and if the records of the pulse-rate or the body weight furnished what we required there would be no place for these measurements. But it is not difficult to demonstrate that the latter are far from constant and reliable guides in treatment and prognosis. By establishing an early diagnosis there is then ground for hope that cases of exophthalmic goitre will come under treatment at such a stage of the disease that treatment will be promptly beneficial in a fashion not common at present, and that in the control of that treatment these measurements will come to play the part that estimations of urinary sugar play in diabetes. The clinical application of heat measurements owes its inception to the work of Benedict, whose work established the accuracy of indirect methods of calorimetry based on estimations of the gaseous exchange. In clinical practice, therefore, these indirect methods are the only ones used. There are two methods of indirect calorimetry, the open-circuit type developed by Boothby and Sandiford at the Mayo Clinic, and employed in a modified form during the past year at St. Mary's Hospital, as described in these columns,[1] and the closed-circuit type used by Benedict and recently available in this country. Boothby and Sandiford, in their book reviewed in the present issue, have put forward certain criticisms of Benedict's apparatus, and there are others that will occur to anyone who has employed both methods. H. G. Earle and J. S. Goodall, in a paper printed in our issue of April 23rd, discuss some of these criticisms. There is need for an impartial survey of the two methods, founded upon a sufficiently prolonged experience of both.

---

THE HARVARD CANCER COMMISSION.

THE Annual Report of the Cancer Commission of Harvard University, 1919-20, with which is combined the Eighth Annual Report of the Collis P. Hungtington Hospital for Cancer Research, which lies before us, gives rise to some reflections on the progress and course of cancer research in this country and America. The Hospital for Cancer Research was opened just before the war as an adjunct to the Cancer Research Laboratories of Harvard, in which some of the best pioneer work in the experimental study of cancer was carried out. The present report shows to what an extent the hospital service has absorbed the activities of the organisation, which are represented by the care and treatment of 2143 in-patients, and the making of 6105 out-patient visits. The laboratory work (biophysics, Dr. Duane and Dr. Bovie; pathology, Dr. Goodpasture; chemistry, Dr. Lyman) is closely associated with the clinical study and treatment of the hospital material. The Biophysics Laboratory is principally engaged in the problems arising out of the application of radium and X rays to the treatment of cancer, alone or in combination with operation, and Dr. Duane has devised a new X ray tube working at high voltage and giving a radiation eight times as penetrating as the Coolidge tube. The radiation emitted has a wave-length of 0·08 Angstrom unit and suffers an absorption of 16–20 per cent. in passing through the human body. The report, which is formal and business-like, ends with a complete list of 89 papers published from the Harvard Cancer Commission since its beginning in 1900. Roughly, half of these communications deal with the properties of ionising radiations, and since the hospital was opened the papers on other subjects are mainly of clinical rather than pathological interest. Those responsible for cancer investigations in this country will be impressed by the radical manner in which the Harvard investigations have been turned from the purely scientific problems of cancer to the practical work of the care of patients.

THE INTERNECINE VENEREAL CAMPAIGN.

A DISCUSSION reported in our present issue on the desirability of notifying venereal disease showed little unanimity except on its value as applied to ophthalmia neonatorum. In the routine instillation of a silver preparation between the eyelids of a scarcely born child we see the universal acceptance of the principle of prophylaxis, notification, and early treatment—in that order—of one of the venereal diseases. It is logical to argue on purely medical grounds, ethical considerations excluded, that the prophylaxis, notification, and early treatment of any communicable infection is desirable. All this is familiar debating ground, while it remains true that as far as the infant victim is concerned it matters not whether the noxa is gonococcus or streptococcus. Perhaps the infant, like the royal prince who was born in Wales and spoke no English, might afford a basis of reconciliation between two opposing camps. We have received, in common with the lay press, correspondence which has passed between the Society for the Prevention of Venereal Disease and the National Council for Combating Venereal Diseases. The Council had submitted to the Society a memorandum defining its policy. In brief, this policy advocates propaganda to induce chastity and popular instruction in sex hygiene and cleanliness as the surest means of combating venereal diseases. The Council points out that no legal difficulty exists to prevent the purchase by individuals of disinfectants as a protection against these diseases, but deprecates the issue of official instructions which would, in its opinion, lead not only to the appearance of official condonation, but to the assumption that such disinfectants are an official guarantee against disease. Also, that if the instructions were not properly understood, aggravation of incidence of disease and attempts at self-treatment might result. The Council recommends that the existing ablution or disinfecting centres should be continued, but should be regarded definitely as experiments subject to careful and official supervision from which accurate and wide experience may be obtained, so as to afford a trustworthy basis for any decision as to their extension. The Society, on the other hand, points out the futility of drawing the line at a domestic standard of cleanliness, and regards as illogical the recognition of unofficial disinfectants handed out with oral directions as opposed to official disinfectants issued with written instructions. It is a nice point, but the issues in such a complex ethico-medical problem are hardly as simple as the Society would have us believe. It is conceivable, to us at least, that the value of immediate disinfection might vary with the sense, sex, age, or general habits of the person affected.

MELANOGLOSSIA.

A CASE of this somewhat rare condition is reported by Dr. Heyninx, of Brussels.[1] The patient was a man of 77, a confirmed smoker. The black patch was in front of the circumvallate papillæ, the commonest situation in which it is found. It was covered by a thick coat of black filaments half a centimetre in length. Biopsy showed hypertrophy of the villi; epithelium thickened and "mortified." The chorion of the mucosa was infiltrated. The papillæ were elongated by hyperkeratosis. Apparently the *Rhizopus niger* was not found in this case, though Dr. Heyninx mentions that it has been observed by others. He sums up the ætiology of this condition as follows. Predisposition is due, first, to general debility resulting from old age or syphilis, and, secondly, to chronic irritation of the tongue. Glossitis then supervenes, with infiltration of the chorion. Finally, epithelial thickening with hyperkeratosis of the papillary filaments and inflammatory pigmentation. The *Rhizopus niger*, when present, would tend to increase the inflammatory processes. The hairy filaments serve to differentiate true melanoglossia from pigmentation due to Addison's disease or to other causes, such as the inheritance of negro blood.

"BE SURE YOUR SIN WILL FIND YOU OUT."

IN "Notes upon the Preparation of Monographs and Reports for Publication" the Medical Research Council gives advice which, coupled with that contained in Sir Clifford Allbutt's standard work on the subject, should, if perchance it be followed, materially help to prune the often over-luxurious tangle of scientific writings. There are two aspects of this subject which deserve special comment, both referring to sins of omission. Much scientific research leads to blind alleys, the charting of which is often almost as important as that of avenues leading to success. Indeed, an apparently fruitless piece of research, if conducted on scientific lines, may be of far-reaching importance, not only in saving other investigators from vain repetition, but also in yielding information which, viewed from some new angle, may shed a flood of light. In the past, unfortunately, an enormous amount of such temporarily negative spade-work has been ignored; but it is to be hoped that, under the auspices of the Medical Research Council, it will be better utilised, and that the comparatively thankless task of charting blind alleys will not be left as an embarrassing monopoly to a few altruistic workers. When we pass from temporarily negative research to the subject of mistakes and disasters, we are faced with certain elementary psychological problems. Mistakes and disasters are often singularly instructive, but their perpetrators do not always experience an overwhelming desire to benefit mankind by confession. Yet if the publication of such errors is left to others than their authors, a garbled version may be the result, and an incorrect impression given both as to the nature and frequency of the error, and the candour of its author. Within the past few months two professors of medicine on the Continent have been pilloried in medical journals on this score. Both were pecuniarily interested in remedies which they had personally devised. Both published a practically unbroken series of successful results, and it was left to others to collect and publish with unaffected glee the not infrequent cases of failure or serious injury inflicted by these remedies. Had these records of failure been published by the authors of the remedies concerned, their own reputation for candour would not have suffered at all, and the reputation of their remedies would have suffered less. It would, however, be unjust to brand as knaves those who do not publish their mistakes; *populus vult decipi* is a law applicable to others than the grossly illiterate, and the advocate of a remedy whose mental astigmatism allows him to see only an unbroken series of successes may be more fool than knave. With regard, however, to such perennial mistakes as the legacy of a swab in the peritoneal cavity it should be borne in mind that secrecy is the mother of rumour, and that, as the drummer said: "Honesty, I have found, is the better policy, having tried both."

---

[1] Le Scalpel, April 2nd, p. 349.

THE BLOOD PRESSURE IN MENSTRUATION.

THE question of the changes in blood pressure before and during menstruation is of no little interest, both theoretical and practical, for it may account for many symptoms; yet it is strange that in most of the text-books there is very little to be found of an authoritative nature bearing on this, and in several works on blood pressure it seems to be ignored. One of the few references to the matter is in Dr. Blair Bell's "Principles of Gynæcology"; another mention of the subject is contained in J. Novak's "Monograph." A brief note by C. D. Mosher, published in the Johns Hopkins Hospital Bulletin, 1901, may also be mentioned. We understand that Professor Winifred Cullis, D.Sc., has conducted some investigations on the question at the London School of Medicine for Women, but the work has not yet been published. In another column of this issue of THE LANCET will be found a query on the subject, and it would be interesting to our correspondent and to many of our readers to have some definite account of the blood pressure changes in connexion with menstruation.

BACTERICIDINS.

THE interesting paper in our present issue by Dr. J. W. McLeod and Mr. P. Govenlock on the production of bactericidins by micro-organisms raises a number of questions which cannot fail to influence the study of immunity. The subject is one which has hitherto aroused remarkably little attention in English bacteriological literature. We are familiar with the fact that one species of bacterium may outstrip its fellows in growth on artificial media owing to the chemical composition of the medium, the temperature of incubation, and other circumstances. This is met with daily in the cultivation of throat swabs and in the isolation of acid-fast bacteria from a mixed flow, to name two instances at random. But the bactericidal effect which one organism may have upon another—even on another variety of its own species—excites little comment. And conversely we are almost equally ignorant on the question of symbiosis. By means of an ingenious modification of Eijkman's agar disc method Dr. McLeod and Mr. Govenlock have studied the bactericidal substances elaborated by the pneumococcus and a number of other species. The results are in several instances very striking. The pneumococcus, for instance, appears to have a definite inhibitory effect not only on organisms of other groups but also on other varieties of pneumococcus. It is also interesting to note that ubiquitous organisms such as the staphylococcus and the colon bacillus show less inhibitory powers. The inhibitive substances appear to be "relatively labile bodies destroyed by heat at 80°–85° C." and need a free supply of oxygen for their production. From the immunological aspect of the question we are tempted immediately to ask if these bactericidal substances are related to the bacteriolytic substances produced by certain tissue fluids, blood serum, and phagocytes. On the practical side of clinical pathology a large number of issues are raised. Not the least interesting, in addition to the questions suggested by the authors, is the presence or absence of these bactericidal substances in the group of obligate aerobes such as the tubercle bacillus on the one hand and obligate anaerobes such as the tetanus bacillus and its allies on the other. As the authors point out, some very interesting lines of investigation are opened out, and we trust that a stimulus has been given to research in a field which has hitherto been more or less of a "dark continent."

THE CAUTERISATION OF PLEURAL ADHESIONS.

WHEN, at the International Medical Congress in London in 1913, Professor H. C. Jacobaeus gave an account of his preliminary attempts to convert a partial, artificial pneumothorax into one that was complete by the division of pleural adhesions with the thermo-cautery, he roused some interest and much sceptical criticism. Those who were present at his lecture may remember how unconvinced several of his hearers were; his method was regarded rather as a clever and daring freak than as an operation calculated to prove of general utility in lung collapse therapy. Subsequent events appear to have belied this early judgment, and in his most recent publication[1] Jacobaeus is able to show that this operation has already been performed in about 100 cases, with brilliantly successful results in several, and without a single operative death from hæmorrhage, air embolism, or other cause. His own cases number 40, and in 30 he succeeded in collapsing the lung by the severance of adhesions. In four of these 30 cases the operation provoked a tuberculous empyema from which only one of the four patients recovered. In the remaining 26 cases the conversion of a partial to a large pneumothorax proved of great benefit owing to the improved immobilisation of the lung. A reference to Professor C. Saugman's[2] recent paper on pneumothorax treatment of pulmonary tuberculosis will show how greatly the benefits of this treatment depend on the completeness of the immobilisation achieved, and his comparison of complete with incomplete cases of pneumothorax may be taken as the measure of the value of Jacobaeus's operation. In about 50 per cent. of his cases the cauterisation gave rise to a pleural effusion. This was, in many cases, simply due to thermal irritation, and it disappeared in a week or two without causing any permanent ill-effects. Far more serious were the four cases of pleural effusion which subsequently turned into chronic tuberculous empyema. This, then, would seem to be the gravest complication which the operator need anticipate, and it alone was the cause of the post-operative mortality of 8 per cent. to which Professor Jacobaeus confesses. Only in one case did he see a hæmorrhage amounting to as much as 100 to 200 c.cm., and he suggests that this complication can be largely avoided by not heating the cautery to more than a dull red glow. Other complications such as surgical emphysema did not threaten life, and complications such as septic infection of the pleural cavity by injury to the lung did not occur once, although spread of mixed infection from a cavity in the lung to the pleural cavity has been dreaded as a sequel to this operation. Thus, the most serious objection to this treatment seems to be the possibility of a tuberculous empyema, and Professor Jacobaeus admits that there is little prospect of eliminating this risk altogether by improvements in the technique of his operation. An account of the technique was given in 1919 by Dr. W. Holmboe.[3]

KERATOSIS DIFFUSA FŒTALIS.

UNDER the name of keratosis diffusa fœtalis, sometimes known as ichthyosis congenita, Dr. Julius H. Hess and Dr. Oscar T. Schultz,[1] of Chicago, who report an illustrative case, describe a congenital anomaly of the skin of unknown ætiology, characterised by diffuse, usually general, hyperkeratosis and qualitatively abnormal cornification of the skin, with decreased exfoliation of the epidermis. This combination of processes causes the formation of thick, horny scales, with intervening deep fissures, the skin resembling a horny cuirass. Secondarily it results in arrest of development and in deformities of the external ears, eyes, nose, and lips. The course of the disease depends primarily on the intensity of the skin changes, according to which the cases have been classified by Riecke into the three groups of keratosis diffusa fœtalis, keratosis diffusa fœtalis mitior, and keratosis diffusa fœtalis tarda. In the first group the abnormality is so extreme at birth that the infant does not survive more than a few days. In the second group the condition, though present at birth, is not developed in such an extreme degree. In the third group the skin anomalies are only slightly developed at birth, or the infants may be born without any visible changes in the skin or of the face. It is only after days, weeks, or months that the symptoms reach the degree present in the second group. The essential pathological changes in keratosis diffusa fœtalis are a marked increase in the horny layer of the epidermis and abnormal keratinisation of the epithelial cell structures. The hyperkeratosis, which becomes the predominant element in the morbid process, is believed to be the result of a preceding stage of hypertrophy and hyperplasia of the skin. In the case now under review the thyroid was undifferentiated and morphologically non-functioning, but the writers maintain that thyroid deficiency cannot be regarded as an essential factor in keratosis diffusa fœtalis unless it occurs more frequently or more uniformly than the literature indicates.

ATMOSPHERIC CONDITIONS AND EFFICIENCY.

ATTENTION was recently drawn in these columns[2] to an interesting report of the Industrial Fatigue Research Board based upon the use of Dr. Leonard Hill's instrument, the kata-thermometer, in boot factories in this country. Another report,[3] emanating from South Africa, indicates that this instrument is also being used in other countries. The research reported upon by Dr. A. J. Orenstein and Dr. H. J. Ireland, working in the Rand gold mines, is the first effort known to us to estimate scientifically the effect of atmospheric conditions upon output and fatigue; for although Dr. Hill has insisted upon the importance of ventilation in relation to bodily activity, he has relied principally upon the increased strain thrown upon the circulation in secreting sweat in order to dissipate heat as the indication of reduced capacity for work. The article under review opens with an excellent summary of physical fatigue and methods of estimating it, and of the work done by Haldane on respiration and Hill on ventilation. The authors devised two forms of ergometer: one was constructed to simulate closely hand-drilling, the type of work which causes the greatest amount of fatigue in gold-mining. In this apparatus blows of a hammer are communicated to a metal disc and, through its deflection, to a column of water which actuates a piston; the movements of the piston are recorded on a revolving drum. The second ergometer was essentially a band-brake dynamometer driven like a winch. Every revolution made by the operator represented so much work done for a certain net pull on the brake pulley. The observer had only to note and take periodical readings of a revolution counter. Two native "boys," one a finely developed Xosa, aged 40, and the other a sturdy Basuto, aged 35, were employed to work these instruments first on the surface and then in various places in the underground workings; meanwhile, atmospheric conditions were observed by using the kata-thermometer, wet and dry, and taking ordinary wet- and dry-bulb temperatures. Observations were also made on the "boys" as to loss of weight, and skin and mouth temperatures. Conditions underground were observed as found, and also after stirring up the air where oppressive, by a fan introduced for the purpose. Many difficulties were experienced, as must always be the case when experimenting under industrial conditions. After due allowance made for these, the writers consider a definite relation to be established between working efficiency and the dry cooling power of the air. If efficiency is placed at 100, with a cooling power measured by the dry kata-thermometer of 6, it falls to only 50 when the cooling power falls to 1. The value of air movement alone was shown by use of the fan placed so as to blow a current of air over the "boys"; in one case an increase of 46 per cent. of output, and in another of 32 per cent. was obtained. The relation between cooling power and output having been determined in this way, observations were made throughout a representative section of a mine. The cooling powers, estimated working efficiency, the number of men, and equivalent number at full efficiency were then ascertained, and the important conclusion arrived at that 21 per cent. of output was being lost through inadequate cooling power. "This loss is loss of output and does not include the losses due to the increased morbidity which must surely follow on the excessive strain and fatigue associated with work in oppressive atmospheres; such losses would be hospital charges and cost of replacing sick men." We have here an instance of the importance to the economics of industry of studying the economics of humanity. Which costs most? The loss of 21 per cent. of output with its attendant increase of morbidity, or the cost of increasing the cooling power of air in the mines?

A laboratory worker reading this report may find much to criticise from the point of view of strict scientific control of observations; he may object on principle to the value of ergometers to measure output as being under the entire control of the operators; he may point to the influence of practice effect, and stress the difficulty of controlling the doings of the subjects outside working hours. Such things, however, must always be encountered under industrial conditions, and Dr. Orenstein and Dr. Ireland are fully alive to their importance. They are to be congratulated on having carried out a difficult and important research, and on having obtained definite and practical results. We hope that this work will be carried further, and that some of the more usual methods of measuring output rather than using ergometers may be employed for estimating efficiency in this country when trade revives. Some of the repetition work, so frequently referred to, should lend itself to hourly and daily computation, and so provide conditions for observation.

SYPHILIS OF THE INTESTINE.

Dr. Udo J. Wile, professor of dermatology and syphilology of the University of Michigan, to whose paper on syphilis of the pancreas we recently drew attention,[1] has added to his studies on visceral syphilis an article on Syphilis of the Intestine.[2] He remarks that though with the exception of syphilis of the rectum intestinal syphilis is rarely met with clinically, the condition is well recognised pathologically both in syphilis of the newborn and in the acquired disease. A study of the literature shows that by far the largest number of cases of intestinal syphilis occur in the small intestine, the jejunum being more frequently involved than any other part. Syphilitic involvement of the cæcum has

been described by Vantini, syphilis of the appendix by Trinkler, and syphilitic ulcers in the descending colon by Borchard, Rotter, and Kummel. Syphilis of the descending and transverse colon was found by Gross. The changes usually occur late in the disease, and are therefore manifestations of the tertiary period. A secondary catarrhal enteritis, however, sometimes occurs, associated with the exanthem of the secondary period; it differs from simple catarrhal enteritis in not yielding to ordinary measures, but disappearing promptly on antisyphilitic treatment. In cases in which an autopsy has been performed, when the patients have died with early syphilis, discrete patches of erythema and swelling of the lymphoid follicles have been found in the intestinal mucosa. In view of the frequent involvement of the spleen, liver, and heart at an early stage, it is not surprising that the mucous membrane of the intestine should be similarly affected. The symptoms do not differ from those of acute enteritis due to any other cause. The cases usually run a mild course, being readily amenable to treatment, and even without treatment tend to disappear spontaneously. Late syphilitic enteritis, though occasionally recognised during life, is more frequently found post mortem or at operation. The symptoms depend on the situation and type of the lesion, and therefore present the clinical picture of ulcer, abdominal tumour, stenosis, or intestinal obstruction. When there are numerous ulcers, particularly in the jejunum, the condition is identical with that of tuberculosis. There may be more or less fever, there is diarrhœa with occasional periods of constipation, and as partial healing occurs cicatrisation takes place with symptoms of partial obstruction. When the lesion is situated near the ileo-cæcal valve or appendix the symptoms may simulate appendicular colic. The relatively uncommon condition of amyloid disease of the intestine due to late syphilis is never recognised until the autopsy, the symptoms being those of chronic ulceration, enteritis, or of amyloid disease due to inveterate syphilis, with no symptoms referable to the gastro-intestinal tract. Owing to the failure of diagnosis and the possibility of complications, such as intestinal obstruction and perforation, the course of the disease is usually fatal, but cases may drag on for years with vague intestinal complaints.

THE EARLY STAGES OF THE HORSE-FLY.

IN a monograph of 204 pages, with numerous excellent plates, Dr. Werner Marchand[1] gives a comprehensive history of the early stages of tabanids. Isolated facts about these flies, occurring in scattered articles and in various languages, have been here collected and reviewed, and presented in an accessible and convenient form. The limitation and repression of the activities of this fly, which plays a considerable part in transmitting disease to horses and cattle, can be effected only with the help of exact knowledge as to its life-history and habits. Two interesting facts emerge which may bear on the steps taken to stamp out these flies. One is that probably the majority of tabanids have only one brood a year; the other is that the larva grows very slowly after hatching and often takes six months or more to become fully grown; moreover, it then remains buried in mud or sand for a time (the so-called resting period). Another piece of information that may help us to control the number of the flies has been elicited. Masses of eggs are deposited usually on plants or sticks at the edge of ponds, streams, and lakes, and even on stones above the water, but seldom on dry ground. From these vantage points the larvæ drop into the water or on to the ground, according to the egg-laying habit of the species, and it is before they reach this stage that our best chance of destroying them would seem to lie.

---

APPENDICITIS IN THE SAC OF A FEMORAL HERNIA.

THE appendix is very rarely found in the sac of a femoral hernia. Keen states in his book on Surgery that he has operated on 140 cases of femoral hernia and not found the appendix in 1, while in 1874 cases of inguinal hernia he found the appendix in 36. Dr. A. D. Hoidale has just reported[1] the case of a woman, aged 60 years, the mother of several children, who consulted him in 1916 for a right femoral hernia which caused no discomfort and disappeared on lying down. She declined operation. On August 26th, 1919, he was called to her. On the 23rd she went to bed as usual, but next morning noticed pain in the right leg on trying to rise and found that the hernia had not disappeared as usual during the night. She stayed in bed and on the 25th nausea began. On examination the temperature was 100° F., the pulse 130, weak and irregular, and the face flushed. The swelling in the groin was about the size of a hen's egg, tense, and tended to redness. There had been stools each day, which became progressively smaller. On the 27th she was removed to hospital, and the swelling became redder. On the 28th an incision was made under local anæsthesia. Pus gushed out and a necrotic mass, so adherent that its structure could not be differentiated, was found. What looked like the appendix, but was thought to be more probably Fallopian tube, was seen. On pulling on the mass, what appeared to be discoloured bowel was seen at the base. The case being desperate, it was decided to open the abdomen in the middle line. In the femoral opening was found a large mass of omentum, the appendix, and a small portion of cæcum. All except the cæcum were necrotic. After cleansing, the whole was pulled back into the abdomen and out through the abdominal incision. At this stage it became necessary to give a little ether. The necrotic sac, omentum, and appendix were removed and drains were put in through the femoral opening and at the bottom of the abdominal incision. Except for some fat-necrosis in a small portion of the abdominal incision and a parotid abscess, recovery was uneventful. Evidently appendicitis in the sac had led to abscess. The adjacent cæcum had begun to take on a necrotic aspect, but not sufficient to warrant the additional risk of resection.

THE Croonian lecture to the Royal Society will be delivered on Thursday, May 5th, at 4.30 P.M., by Dr. Henry Head, F.R.S., the subject being Release of Function in the Nervous System.

A KNIGHTHOOD has been conferred on Dr. James Craig, King's Professor of Practical Medicine, School of Physic, Trinity College, Dublin, Physician to Sir Patrick Dun's Hospital, and Past President of the Royal College of Physicians of Ireland.

THE death occurred on April 23rd after prolonged illness of Mr. Henry Edward Juler, consulting surgeon to the Royal Westminster Ophthalmic Hospital, and consulting ophthalmic surgeon to St. Mary's Hospital, who was for long a leader of ophthalmological thought and practice in this country.

FARADAY SOCIETY.—A general discussion on Physico-chemical Problems Relating to the Soil will be held during the afternoon and evening of May 31st, in the rooms of the Chemical Society, Burlington House, London, W., Sir A. Daniel Hall, F.R.S., in the chair. The discussion will be opened by Dr. E. J. Russell, F.R.S., director of the Rothamsted Experimental Station, who will give a general survey of the subject. A series of papers dealing with soil moisture, organic constituents, adsorption and colloidal phenomena will then be put forward as a basis for discussion. Further particulars of the meeting may be obtained from the secretary of the Faraday Society, 10, Essex-street, London, W.C. 2.

EXAMINATION OF WOUNDED PENSIONERS:

SOME PRACTICAL SUGGESTIONS.[1]

BY A. E. CHISHOLM, F.R.C.S. EDIN.,
SURGICAL SPECIALIST, MINISTRY OF PENSIONS, DUNDEE.

IN the examination of pensioners who have sustained wounds the smallest and most obvious points have often considerable importance in forming a proper conclusion as to the just assessment of a disability. The primary condition can often be pictured and contrasted with present deformity and functional disturbance; severe wounds sometimes have a much better result than was hoped for, and vice versa. For example, a man with a large scar over his scapula, involving considerable loss of muscle and bone, may yet retain a degree of function only justifying a comparatively low assessment. On the other hand, a through-and-through rifle or machine-gun bullet wound, healing rapidly, may be the cause of severe and perhaps permanent injury by severing an important nerve.

It is a good plan to deal with each kind of structure in turn—scar, muscle, bone, &c.—and then to pass on to function. The amount of gross injury does not so much matter, within limits, as the extent of interference with function. Facial disfigurement naturally falls into a category by itself. A few points will now be discussed in the above manner.

Scars.

The points usually noted about scars are: (1) Extent; (2) healed or unhealed; (3) strength of scar; (4) adherence (*a*) to subjacent soft structures, (*b*) to bone; (5) form—e.g., puckered; (6) tenderness.

In some scars there may be a thin and recently healed part which breaks down periodically. If the present state of healing has only lasted for a few weeks, the condition should not be considered as stationary; there is the possibility of a retained foreign body or of a sequestrum being the cause of the intermittent sinus formation. A scar adherent to bone is not always unsatisfactory. With a moderately good blood-supply to the scar and firm healing for several months there is no reason to anticipate a breaking down unless there is injury by direct violence, in which case a scar adherent to bone, being less resilient, is more liable to break down than a scar adherent only to soft tissues.

In order to test if a scar is adherent or not to muscle the man should be instructed to contract the underlying muscle voluntarily. The dragging due to adherence may be missed if only passive movements are employed. Adherence to muscle is usually more crippling than adherence to bone. Good judgment is required with regard to tenderness. There is probably a little malingering on this score; apparently excessive signs of pain on pressure may be circumvented by the recognised ruse of directing the man's attention to another part and pressing on that part, while all the time a careful and *increasing* pressure is being applied to the painful scar. The extent of the scar, if not tacked down, is not generally of much consequence unless facial disfigurement is involved.

Atrophy.—Limbs must be measured circumferentially at the same level and with complete relaxation of the muscles concerned. A true measurement, to express atrophy, should as a rule not be taken over the site of the scar, especially if there has been loss of tissue, but over the most fleshy part of the limb, as muscles generally receive their nerve-supply not very far distal to their origins. The thigh should be measured in the upper half; the forearm should be measured 1½ to 2 inches below the bend of the elbow. For practical purposes the thighs and calves may be considered relatively equal, but the same does not apply in the case of the upper limbs. In a right-handed man the right arm is naturally better developed than the left. The proper way to record arm measurements is as follows:—

Right upper arm ...	10½ in.	Right forearm	9¾ in.
Left " " ...	10 in.	Left "	9½ in.

Right-handed or left-handed (as the case may be).

Testing Muscular Movements.

In testing the function of muscles the limb must be in a proper position to give the muscle a fair chance to do its work; but sometimes the action of one muscle group may be simulated by that of another muscle group, as the following example will show.

Imagine that the metacarpo-phalangeal joints of one hand cannot be actively extended by thirty degrees. There may have been a musculo-spiral nerve injury that had recovered, but the extensor muscles have not fully recovered their tone and have become stretched. The fingers can, however, be extended passively. Now ask the man to flex his wrist, and at once the digits will be fully extended. The reason is obvious; the flexion of the wrist has increased the distance between the origin and insertion of the extensors, and thus the elongated muscles have, for the time being, become taut, resulting in the extension of the digits. Nevertheless, extension is impaired; the apparent voluntary extension is a mere camouflage.

Fibrosis amongst muscle fibres.—Those whose privilege it has been to deal with wounds in their early stages, as in the casualty clearing stations, are well aware that in a muscle wound, even apart from loss of tissue and destruction, the divided ends of the muscle fibres tend to separate widely, and the gap has to be filled in by fibrous tissue. Even if the wound has not been deep the fibrous tissue formation may be considerable, and the contractile power of a given muscle may be seriously and permanently impaired. Such cases should often be assessed more highly than outward appearances seem to indicate. If the muscle is tacked down to bone the interference with function may be very great. In the instance of fractured femur with considerable muscular injury the scar tissue of the quadriceps may have become so firmly fixed to the femur at the site of fracture that the knee is practically ankylosed, although the joint itself is entirely free from any morbid condition.

Bones.

A case of ununited fracture is not often met with at a pension board, but one is occasionally seen in the upper limb. In the humerus the disability is a serious one, but in ununited fracture of the ulna or radius the uninjured bone may largely compensate for the lack of continuity of the other. If both bones of the forearm are ununited the condition is bad indeed. If operative treatment has definitely failed, and an expert has advised against a further attempt, it may be possible to supply a fixing apparatus to act as a sort of exo-skeleton. It is, however, more common to find a bone firmly united in *poor or bad alignment*; *in the forearm* this condition may interfere with rotatory movements—a supinated forearm which cannot be pronated is functionally much more impaired than a pronated forearm which cannot be supinated.

Good alignment in the lower limb is of importance for weight-bearing. An angled femur, concave outwards, may throw great stress on the internal lateral ligament of the knee-joint; angled with the concavity inwards it may require elevation of the pelvis on the affected side in order to bring the foot vertically below the hip-joint, or the man may have to walk with an awkward and ungainly gait with the affected limb abducted at the hip. If the pelvis be raised an *apparent shortening will result, although there may be* neither loss of bone nor overlapping of fragments. A raised boot may then be required. It may here be remarked that raised boots have often been supplied too high.

Many mistakes are made in measuring the length of the lower limbs. The anterior superior iliac spines should be accurately located and marked—not always an easy matter if there is much subcutaneous fat present. With the man lying on his back the anterior superior spines should be on the same transverse level—i.e., the pelvis should not be tilted. The limbs must be in a similar position very slightly abducted, just beyond the parallel, and equally so. Any difference in the lengths measured from the anterior superior iliac spine to the tip of the internal malleolus *will indicate the true shortening.*

In an ankylosed hip with adduction instruct the patient to lie on his back with his lower limbs in the same relative position to each other as if he were standing, or else have him standing up. Then measure from the umbilicus to the internal malleoli. Apparent shortening is caused by tilting of the pelvis. In fracture of the leg below the knee a convenient method is to let the man lie on his back with his hips and knees flexed and with the heels resting on the couch, and to measure from the upper border of the internal tuberosity of the tibia to the tip of the internal malleolus. Shortening of the upper arm, unless very pronounced, need not of itself demand extra assessment.

Joints.

Ankylosis.—Statutory assessment is laid down for ankylosis of joints, but it must be remembered that this applies to fixation in the most advantageous positions.

---

[1] Being the substance of a paper read before the Ministry of Pensions Medical Club, Dundee, on Feb. 19th, 1921.

(1) A shoulder-joint should be ankylosed in the abducted position to upwards of 80° with a little forward inclination of the humerus and slight internal rotation at the shoulder-joint. The scapula is thus given free movement and the arm can be brought to the side, the lower angle of the scapula rotating inwards. This is greatly aided by gravity. But if ankylosis has taken place with the arm at the side and the scapula in its normal vertical position function will be greatly impaired, as it will be found impossible to abduct the arm through more than a very few degrees.

(2) The best position for ankylosis of the elbow depends a good deal on the man's work. For most purposes it is probably best to have the forearm flexed at rather less than a right angle with the upper arm. If rotatory movements are also lost the best position for the forearm is in fairly complete pronation. A forearm fixed in supination, especially with an ankylosed elbow, is in a very bad functional state.

(3) The wrist is best ankylosed either straight or slightly dorsiflexed. A flexed wrist means a hand with a somewhat weakened grip.

(4) The hip is best ankylosed in slight abduction with full or almost full extension. Walking can then be performed by a swinging movement of the pelvis.

(5) The knee should be ankylosed in full or almost full extension. There is sure to be considerable atrophy of the thigh on the affected side, but the calf will not be atrophied unless from some other cause, and may even be increased in circumference because of the extra work put upon it.

(6) The ankle should be ankylosed at right angles. It is obvious that a fixed ankle-joint, with the foot pointing even a little downwards, is a cause of considerably greater inconvenience than one in which the rectangular position is maintained. The disability is accentuated if a hallux rigidus is also present on the same foot.

A flail joint is almost always a cause of greater disability than an ankylosed joint. This applies to the upper limb. In a lower limb amputation may be the only possible form of treatment, but instances of this condition are not often seen at pension boards.

Movements.—The examiner should, of course, know the normal limits of movement of the various joints. For example, pronation of the forearm is a movement which is not quite so complete as is often imagined; probably it is frequently tested for in the wrong way, and rotation at the shoulder takes place and deceives the examiner. The movements of the two limbs should be compared; the elbows should be firmly applied to the flanks and flexed at a right angle, and the man should be directed to pronate both forearms slowly and fully; then rotation at the shoulder will not take place. If a man does not seem to be able to pronate at all, or only a very little, direct him to bring the palm of his hand to the back of his neck. He requires semi-pronation to achieve this movement, and it may be found that in this way he can do more than he thought he could.

If two distal phalanges are missing from a finger the remaining phalanx may appear, quite wrongly, to have a limited range of flexion. The gap left seems to deceive somewhat. Normally the proximal phalanges can be flexed almost, or quite, to a right angle with the metacarpals. Whether phalanges are lost or not, the movements at the four inner metacarpo-phalangeal joints should be tested together and not separately. If tested separately a limitation of flexion may be described which does not really exist. The estimation of grip by percentage is a very difficult proposition, and is very often guessed at quite wide of the mark.

In examining for joint movements of the lower limbs the trousers and pants should not be left on. In testing for flexion of the hip in the dorsal position the sound hip must be fully extended and the sound thigh kept in firm apposition with the couch, otherwise the limitation of flexion, if any, may be considerably underestimated on account of the pelvis tilting forward, the lumbar spine becoming less concave backwards. Examiners frequently describe grating in the knee-joints when there is nothing pathological about them. A certain amount of friction between the patella and the condyles of the femur is quite normal.

Sensibility.—In testing for anæsthesia the general distribution of the main cutaneous nerves must be borne in mind. Not unusually the examiner merely asks the man if he feels a touch in certain places; this is not sufficient, for a man may feel a touch less acutely than he ought to do. The corresponding parts on the two sides must be tested in a similar way.

The Question of Treatment.

Treatment should not be pressed on a man if the relief gained must of necessity be small or the result doubtful, especially if the man's economic position will cause him difficulty. If the case will certainly be improved by treatment the man should be advised to have it; if there is no hurry from the point of view of ultimate result it is often well to recommend postponement (to suit the man's economic convenience) provided that treatment is not too long delayed. Large pensions naturally cannot be paid to men who may be cured or improved.

A good working rule is as follows. If in doubt recommend the man for expert advice, with a view to treatment if deemed advisable. In cases of ankylosis of joints in bad position operation for rectification and re-ankylosis, or even formation of a false joint, must be considered. With a flail joint, and if operation has already been decided against on expert advice, the supply of a suitable apparatus must be thought of. Where a nerve has been divided or destroyed and if nerve suture has failed, a sufficient time having elapsed to test its possibilities, tendon transplantation may still be feasible, or even arthrodesis might be indicated. Other examples might be added.

It is not necessary to go into very elaborate detail with the cases. A fair estimate of functional disability and curability is all that is required. The ideal is to take a wide general view of the case, to know what to look for, and to do the examination in a systematic and deliberate way.

No pretence is here made of giving anything like a full account of the examination of wounded pensioners; this paper is merely a collection of a few conclusions arrived at during fairly wide experience of pension board work; but in spite of the elementary nature of the points discussed, or because of it, I think they may be found useful on application.

TUBERCULOSIS.

Position of Sanatorium Superintendents under the Ministry of Health.

IN a memorandum dated March 31st the Ministry of Health has drawn attention to the special arrangements to be made on and after May 1st for the provision of treatment in residential institutions for tuberculous ex-Service men in England. Sanatorium benefit ceasing to be included under the National Insurance Acts after May 1st, it has proved necessary to set out in detail the arrangements made with the local health authorities taking over the care of tuberculous ex-Service men. It may serve a useful purpose at once to focus attention on one aspect of these arrangements as they affect superintendents of sanatoriums. Under paragraph 11 the following passage occurs:—

> "It will also rest with the tuberculosis officer, subject to the considerations set out in paragraph 17 of this memorandum, to determine the length of treatment to be afforded to each case admitted to a residential institution. In reviewing from time to time the cases receiving residential treatment the tuberculosis officer should have before him, in each case, periodical reports on the patient's condition and progress from the medical superintendent of the institution in which the case is being treated."

According to paragraph 17—

> "The Minister of Health reserves the right to call for the reconsideration of cases by the tuberculosis officer, and for this purpose to ask for special medical reports from him on particular cases, where necessary, and he may afterwards terminate liability for the cost of treatment of any case after a certain date."

It appears from these instructions that a tuberculosis officer may overrule a medical superintendent in the conduct of a case under the latter's care. The decision as to the duration of treatment being put into the hands of the tuberculosis officer, it follows that he may also, to a certain extent, dictate the nature of the treatment given in an institution, for time is an essential factor in the choice of treatment. A medical superintendent may consider a course of specific treatment for six months or more indicated in a given case, but knowing that such a course may be arbitrarily interrupted at any time, he may attempt nothing more than palliative tinkering. On the other hand, the tuberculosis officer may continue to keep in a sanatorium patients whom the medical superintendent may have found to be unsuited for this treatment; both superintendent and patient may agree on this [illegible] yet their wishes may be disregarded by the tuberculosis officer. Even with free hands, a sanatorium medical officer is apt to find his work monotonous and to slip by imperceptible stages from the status of a keen clinician to that of an administrative hack. Robbed of stimulants to initiative and the sense of responsibility conferred by freedom to prescribe only what he considers the best treatment, he is bound to feel aggrieved, and if this arrangement is perpetuated, the sanatorium service will not attract the best type. Yet the successful management of a sanatorium requires many and exceptional qualities, and if this service comes to attract only second-rate men whose chief qualification is docility, then sanatorium treatment will suffer. In Canada this difficulty has recently been thrashed out, and since the inspection of 26 sanatoriums by a board of tuberculosis consultants, the chain of responsibility in such institutions has been reorganised, so that the medical superintendent shall be in complete charge, and shall be the sole channel of communication with the governing board, whether it be civilian or departmental. There are, of course, other sides to this question which bristles with administrative difficulties, but we have dwelt solely on the point of view of the medical superintendent, because it has not, apparently, been sufficiently studied in the drafting of this memorandum, and because the person who must ultimately suffer most from any arrangement, which fetters the medical superintendent unnecessarily, is the patient himself.

Conditions Mistaken for Pulmonary Tuberculosis.

As a result of a study of 1700 consecutive cases admitted to his sanatorium Dr. B. Stivelman, of the Montefiore Sanatorium, New York,[1] indulges in rather uncomplimentary reflections on the diagnostic skill of specialists as well as of general practitioners. It appears that though no patient could be admitted unless the diagnosis of a general practitioner was confirmed by at least one specialist, 176, or 10·4 per cent. of the total, were found to be non-tuberculous. In the past it has sometimes been the privilege of the specialist to lay the blame for faulty diagnoses at the door of the general practitioner, and it is with ill-concealed glee that the sanatorium physician shows up the frequent mistakes of the consulting physician. The matter is, however, rather one of opportunity than of superior skill: the consultant sees a patient only once or twice, whereas the sanatorium physician has unrivalled opportunities for weighing at his leisure the evidence for and against the diagnosis of tuberculosis. Dr. Stivelman finds that chronic bronchitis and emphysema is the condition most commonly mistaken for tuberculosis of the lungs. Other common simulants are mitral disease, neurasthenia, and non-specific diseases of the upper respiratory tract. With regard to this latter class, he indulges in a digressive thrust at the "...... many feverish reports about the great frequency of conjugal phthisis. ......" It seems that in as many as 15 cases acute affections of the upper respiratory tract were diagnosed as tuberculous because the consorts of these patients happened to be tuberculous. "In the light of cold study it would seem that conjugal tuberculosis is accidental."

Sanatorium Benefit in Birmingham.

In a Report of a special subcommittee appointed by the Birmingham Insurance Committee to inquire into sanatorium treatment, some fairly encouraging figures are published showing the results achieved in Birmingham by sanatorium and other treatment. Of 1314 insured persons recommended for sanatorium benefit in 1914, between 40 and 50 per cent. had died within six years, and of 493 survivors traced, 357, or 72·4 per cent., had worked steadily since 1914. While these results are better than those obtained in areas where the problem has been dealt with half-heartedly, they leave room for improvement. Incidentally the fact is mentioned that a large proportion of these cases received an intensive course of tuberculin treatment, one indirect advantage of which was the stimulus it gave the patient to keep in touch with his medical adviser before and after residence in a sanatorium. The facts given in this Report are a useful antidote to the atrabilious analyses of sanatorium treatment published elsewhere, but its recommendations are still more helpful, because they show how, with economy of effort, good results may be bettered. In a recent letter to the *American Review of Tuberculosis*, Professor Fishberg stated that none of the sanatoriums in New York State was filled. There are signs that this may shortly be the case in the United Kingdom, and when this happens, and our sanatoriums are no longer choked by advanced cases shouldering each other out and robbing the early case of a chance to attain to permanent cure by prolonged treatment, sanatorium treatment will be a step nearer to the ideal. Towards this consummation the Report points by advocating the provision of hospital as distinct from sanatorium beds. The former should provide for cases of tuberculosis complicated by other diseases, such as diabetes, which unfit the patient for the general routine of sanatorium life. Such hospital beds would afford a brief respite for workers whose careers of useful part-time work are punctuated at irregular intervals by short periods of impaired health. Though beyond the possibility of permanent cure, these patients need but a few weeks' rest to restore them to part-time working capacity, and this may be prolonged for many years. The Report emphasises the value of prevention, and suggests that "It would be wiser and more practicable to remove infants born into the infected homes of poor consumptives and bring them up for a few years in healthy surroundings than to remove the consumptive parent from the home for the whole period of his infectiousness." This growing movement in favour of preventing tuberculosis in childhood, instead of patching up the patient in adult life, is one of the most hopeful signs discernible at the present time, but in the van of this movement there are, unfortunately, enthusiasts like Dr. Harald Sundelius[2] who, in saving children from their infected parents, would give a Herod-like touch to the proceedings.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Radium for Paris Hospitals.

AT a recent meeting of the Conseil Municipal de Paris it was decided to buy 2 g. of radium for the benefit of a new radium institute under the supervision of the Administration of the Assistance Publique, and a sum of Fr.2,500,000 has been granted for the purchase. The radium will be delivered to the town authorities by the Curie Institute, and the capital acquired from the sale will enable scientists working at this institute to carry out further researches on radium. Mr. P. Mourier, Directeur Général de l'Administration de l'Assistance Publique, has officially expressed a vote of thanks to those responsible for the decision of a grant through which many hospital patients will have the benefit of radium therapy.

Dangers of Radium and X Rays.

At a recent meeting of the French Academy of Medicine Mr. H. Bordier, of Lyons, made an important statement concerning the dangers of radium to those who manipulate it, dangers which, in his opinion, may be greater still than those resulting from exposure to X rays. He pointed out that the ill-effects of radium are revealed by the occurrence of pernicious anæmia resulting from the action of the radium emanations upon the marrow of the bones, this being proved by the pathological findings in rats which have been exposed to radium emanations. In the course of his statement Mr. Bordier mentioned the cases of the nurse and two laboratory assistants reported by J. C. Mottram. In his conclusion he expressed the wish that such harmful effects due to radium emanations should be investigated by the Académie de Médecine. Finally, a special committee has been appointed to study the ill-effects of radium and to suggest preventive measures to save life. The members of the committee are: MM. A. Béclère, A. Siredey, H. Hartmann, P. Delbet, and A. Broca. In the course of the debate Mr. T. Tuffier pointed out that in America it has been recorded that the nurses whose duty it is to clean radium apparatus eventually show signs of atrophy of the ovaries when they are kept too long on this work. This effect on genital glands is slow and insidious but permanent. On account of so injurious an effect upon the genital glands, a frequent shift system has been adopted in American institutions for those members of the staff who manipulate apparatus holding radium.

---

[1] American Review of Tuberculosis, January, 1921.

[2] Tubercle, April, p. 321.

Mr. Adolphe Leray died recently from the effects of X rays. He had been in charge of the X rays department of the Hôpital Saint-Antoine in Paris for 25 years. During the war he radiographed many thousand wounded soldiers, never considering the dangers of constant exposure to the X rays. He was awarded the Legion of Honour for his great devotion. Since the war he had been appointed professor in radiology to the École des Infirmières at the Hospice de la Salpêtrière in Paris. This is the third death due to the effects of X rays which has to be recorded amongst Paris radiographers in the course of the last few months. In a previous letter comments were made upon the death of Mr. Charles Infroit, who died from complications due to dermatitis caused by exposure to X rays.

New Considerations on Cancer.

Mr. H. Reynès, of Marseilles, has recently communicated to the French Academy of Medicine the case of a patient suffering from carcinoma of the breast which was considered inoperable. After removal of both ovaries the tumour, which was ulcerated, healed up and became smaller; by that time there was a marked improvement in the general condition of the patient. Mr. Reynès is of opinion that the malignant growth process has subsided. Considering the well-known action of the ovarian secretion on the development of the mammary glands, Mr. Reynès suggests that a greatly increased ovarian secretion may favour the abnormal growth of the cells in the mammary glands.

National Health Insurance Bill.

Mr. Daniel Vincent, Minister of Labour, has submitted to the Chambre des Députés the text of a Health Insurance Bill and that of an Old-age Pension Bill. These Bills were partly prepared by the present Minister's predecessor, and their introduction was foreshadowed at the last opening of the French Parliament by Mr. Millerand, as already announced. The suggestion of a health insurance scheme has been opposed by the principal Syndicates of Medical Practitioners. Under the proposed scheme, contribution towards the insurance funds would be compulsory for any employee, man or woman, whose annual salary is Fr.10,000 or under. The insurance would be optional for employees working on farms or cultivating the land. Those working entirely on their own or who work assisted by only one employee could also benefit by the Health Insurance Act should they desire, providing that their income does not exceed Fr.10,000. The insured are to be classified in several groups according to salary in this way:—1st group: less than Fr.1200. 2nd group: Fr.1200 to Fr.2400. 3rd group: Fr.2400 to Fr.4000. 4th group: Fr.4000 to Fr.6000. 5th group: Fr.6000 to Fr.8000. 6th group: Fr.8000 to Fr.10,000. Both the employee and employer would have to contribute towards the insurance, the contribution being 5 per cent. of the average salary in each group. In case of illness or accident the insured person would have the right to receive, free of charge, medical attendance, drugs, apparatus, and so forth, but surgical operations could only be performed gratuitously in State hospitals. If disabled, should incapacity have reduced ability to work to the amount of 60 per cent. or more, it is proposed that during the first six months the benefactor would receive a daily allowance of Fr.1.50 in the first group, Fr.3 in the second, Fr.5.25 in the third, Fr.8.25 in the fourth, Fr.11.50 in the fifth, and Fr.15 in the sixth. If work cannot be resumed after six months, monthly allowances are to be given of Fr.45, Fr.75, Fr.110, Fr.140, Fr.195, Fr.250 in the respective groups. Should invalidity last over five years it is proposed to give an annual pension of Fr.500, Fr.900, Fr.1275, Fr.1650, Fr.2325, Fr.3000 in the respective groups. Owing to the attitude of the organisations of general practitioners it seems doubtful whether the panel system will be adopted; a system of remuneration similar to that arrived at in the case of medical attendance to pensioners, described in a previous letter, may be adopted.

April 20th.

AUSTRALIA.

(FROM OUR OWN CORRESPONDENT.)

Public Health.

THE Commonwealth Government has instituted a department of public health, to be placed under the direction of a special Minister, with Dr. J. L. Cumpston as medical director. Federal quarantine will be absorbed by the new department, which will also establish research laboratories in various parts of the Commonwealth. The precise scope of the work to be undertaken by this new organisation is left indefinite, but under the wording of its establishment it is capable of very wide expansion. It is difficult to see what progress can be made so long as each State maintains an entirely independent health service; whenever widespread epidemic disease has hitherto occurred there have been confusion and dispute between differing authorities, or practically complete inaction owing to each authority regarding the matter as one for its neighbour. When State quarantine has been necessary the difficulty has been overcome by making State officials temporary Federal authorities, but this harmonious solution could not be indefinitely utilised.

Melbourne University.

Sir Henry Carr Maudsley, who was appointed lecturer on medicine some ten years ago on the retirement of the late Dr. J. Jamieson, has resigned his appointment as from August 31st next, and the resignation has been accepted with regret by the council. Sir Henry Maudsley retired from the active teaching staff of the Melbourne Hospital last year, and was appointed honorary consulting physician. The scope of the lectureship will be somewhat altered in future; no attempt will be made to cover the whole field of medicine, and those subjects not touched on will be notified to the deans of the teaching hospitals, who may arrange to have them dealt with by their respective clinical lecturers. There is at present no chair of medicine in the Melbourne University, but it is hoped that such an appointment may be made possible in the near future.

Small-pox.

No further cases of small-pox have been reported from New Zealand, and no case has occurred in Australia, although chicken-pox has been prevalent. The s.s. *Kanowna* arrived from Japan, having had on board a case of small-pox which was landed at Hong-Kong. On arrival she had two suspicious cases, which proved not to be small-pox, and after the necessary quarantine she has been released.

Alleged Negligence.

A coroner's inquiry was begun in Sydney in connexion with the death of a boy who had met with an accident and had been under treatment in the Sydney Hospital for 19 days. Death resulted from sepsis following on the application of the "gimlet" extension to an injury of the lower limb. The parents of the boy allege that there was neglect and unskilful treatment on the part of the surgical staff in charge of the patient. After the evidence of the boy's father and mother had been taken the matter was adjourned for further investigation.

March 15th.

Public Health.

SCHOOL MEDICAL SERVICE.

Cambridge.

AT Cambridge the average number of children on the roll in 1919 was 8493, and of these 1246 were medically inspected at the routine examinations, in addition to 156 special cases. Dr. Andrew Laird, the school medical officer, contributes some interesting particulars as to the general physique of the school children in the year under consideration, as compared with their condition before the war, and is of opinion that, on the whole, "the condition of the youngest children up to 7 or 8 years compares favourably with the pre-war records of these conditions, while the older children appear, on the whole, to compare quite unfavourably with children of the same ages in 1913–14." He suggests that this can scarcely be a question of feeding, which would have probably affected all equally, and believes that "daylight saving" has had an injurious effect, together with relaxation of parental control, and the attractions of the picture theatre. Among boys the average weights in 1919 were less than those of the children of corresponding age in 1913 in each year from 6 to 13 inclusive, except at 7 years; so also were the heights, except at 7 and 13 years; among girls the weights were lower in 1919 at every age from 3 to 14, except at 12 and 13; and the heights at every age except 3 and 13. Apart from this measuring and weighing, the opinion of the medical inspector, Dr. Mabel Gurney, as to the child's physical condition, judged by actual inspection, was that among boys 23·7 per cent. and among girls 16·5 per cent. were below the average in 1919, as compared with 16·7 and 13·8 per cent. respectively in 1913. This is a matter of great importance when considered in regard to the country as a whole, for, so far as data are available up to the present, and speaking generally, the nutrition of the children does not appear to have been injuriously affected during the war period. Cleanliness showed some falling off; not at the routine medical inspections, where not a single child was found to be verminous or dirty, but at the nurses' visits, where 26·7 per cent. of the children examined were found to have nits or pediculi. Organic heart disease was diagnosed in 19 children, but treatment was considered necessary in only 1 case, the remaining 18 continuing to attend school "under observation." Not a single case of pulmonary tuberculosis was definitely diagnosed, and six children only were "suspected" to be so suffering, of whom one only was recommended for treatment. The treatment of defective teeth is very fully dealt with by Mr. W. H. Jones, the borough dentist. 6602 children were examined, of whom 51·9 per cent. were treated; the gradual diminution in refusals of treatment is a satisfactory feature. It is pointed out that if there were no refusals there would be no children with unsaveable permanent teeth; parents who have refused in previous years often bring their children for treatment when the permanent teeth have become unsaveable and are tender and aching. It is to be hoped that the object-lesson will benefit the younger children of these parents and that they will perceive that toothache is not a necessary evil, and that unsightly teeth may be a sign of parental ignorance and neglect. Mr. Jones considers that re-examination is necessary at intervals not longer than 12 months. "Schemes involving treatment without re-examination largely represent a waste of time, skill, and capital outlay," says Mr. Jones. The principle of "a stitch in time" is certainly applicable in an especial degree to the care of the teeth; and this is well shown in the tables accompanying Mr. Jones's report.

Northamptonshire.

In Northamptonshire the number of children examined at the routine inspections in 1919 amounted to 7338; this is exclusive of the urban district of Kettering, where elementary education is administered separately. Nutrition was either normal or excellent in 94·10 per cent., and in only six cases was it considered to be "bad." This may be regarded as most satisfactory. The percentage of children with four or more decayed teeth was, however, 31·82. Until the date of this report no systematic dental treatment had been provided for school children. This defect has now been remedied. Tuberculosis of the lungs was either found or suspected in 1·03 per cent., and non-pulmonary tubercle in an additional 0·28 per cent. These ratios are high, and it is noted by Mr. J. L. Holland, secretary to the Education Committee, that in the larger urban areas, where boot and shoe making is the chief industry, tuberculous infection is above the average, and "shows itself in the large number of children kept away for long periods on medical advice on account of pre-tubercular conditions—debility, anæmia, and threatened lung disease." In Wellingborough there are about 70 such cases, and it has been decided to erect an open-air school for 150 children on the outskirts of the town, so that they may obtain their education as far as possible under ideal conditions. Organic heart disease was diagnosed in 157 children (2·14 per cent.), but only 9 were recommended for treatment, the remainder being considered fit to attend school "under observation"; it is not stated whether it is the medical officer or the teacher who has the responsibility for determining the fitness for school life of these 104 children with valvular disease. Vision testing was only carried out among the group of "leavers." The sight was found to be normal, $\frac{6}{6}$ for each eye, in 75·76 per cent.; this is very satisfactory, for in London the corresponding ratio was 43·3 per cent. Dr. C. E. Paget, medical officer of health for the county, who presents this report, states that approval has been obtained for the appointment of a school dentist, and that it is hoped that early in the current financial year a practicable scheme will be evolved for the provision of school nursing, with the coöperation of the County Association.

Nuneaton.

The results of school medical inspection at Nuneaton during 1919 are reported on by Dr. A. Middleton Hewat, who took over the duties of medical officer of health and school medical officer from Oct. 1st, previous to which date the work had been carried out by Dr. G. A. Wolfendale and Dr. Gray Maitland. The number of children examined in the code groups was 1247. The first point noticed is a very unsatisfactory condition as regards vaccination, only 43·3 per cent. of those inspected being protected against small-pox. In London small-pox just obtained a footing in 1918, but Dr. W. H. Hamer reported that the offer of vaccination was, as a rule, gladly accepted by the parents, and no cases of conscientious objection were met with. If the general population could actually realise that prevention is better than cure there would be no difficulty, but at Nuneaton the antivaccinationists are confirmed in their views. Dr. Hewat draws attention to the unsatisfactory condition as regards cleanliness in some of the schools in the town, especially among girls; in two schools the percentages found verminous—i.e., vermin or nits in the head present—were 64·4 (infant girls) and 62·7 (girls) respectively; two prosecutions were undertaken and both were successful. Goitre was found in 18 children (1·4 per cent.); this disease is stated to be fairly prevalent in the town, but most cases are very slight, and cause no inconvenience. (It may be noted in this connexion that in the neighbouring county of Derby, where goitre used to be so prevalent as to be known as "Derbyshire neck," the disease is not even mentioned in the school medical officer's report for 1919). The condition of the children's teeth was by no means satisfactory; 19·1 per cent. are stated to have had "more than four"—which probably means "four or more"—decayed teeth; but of the 239 children included in this category only 16 were referred for treatment. Arrangements have been made to remedy this state of affairs. Only six children in the code groups (1247) were found with suspicious pulmonary tuberculosis, and only five with organic heart disease.

Stirling.

During the year 1919–20 Dr. T. Adam reports that 11,802 children underwent routine medical inspection. The attendance of parents was poor, only 9·5 per cent. being present. Out of 1047 children who had defective vision glasses were prescribed by the school oculist for 399; 87 were taken to a private oculist, 96 had treatment other than glasses, and 238 were awaiting treatment. These cases involved 1513 nurses' visits. Other defects, in number 1556, involved 1643 nurses' visits. With the exception of the entrants, the children in Stirling are both heavier and taller than the Glasgow children. The 13-year-old age group is about half a year under the normal standard both in height and weight. The figures for nutrition show only 3 per cent. of the children below the average. One child had very bad nutrition, while 56 per cent. were above the average. The county has now one full-time and one part-time dentist, accounting for a considerable increase in the amount of cases treated.

Glasgow.

This report is the first issued by the education authority of Glasgow since the reorganisation. Dr. E. T. Roberts deals with the steps taken to cope with the outbreak of small-pox in the schools in the early part of 1920. On receiving notice from the medical officer of health that two children, who had the day before been attending school, had contracted small-pox he at once decided to stop the ordinary medical work in the schools and set the staff to vaccinating those children whose parents gave consent. Accordingly, 14,781 school children were vaccinated, including 6856 revaccinations of children over ten years of age. During the year not one school was shut on account of infectious disease. The number of routine inspections made was 38,047 and 63 per cent. of the parents attended the examinations. An interesting survey of heights and weights for each age is given. Each age-group is, roughly, one year behind the anthropometric standard both in height and weight. Signs of slight rickets were found in 1·8 per cent. of the children. Under "marked rickets" are classified 1·8 per cent. with "knock-knee," 2·4 per cent. with bow legs, 1·3 per cent. with curved tibia, 0·5 per cent. with pigeon breast. Non-rachitic deformities were found in 0·2 per cent. of children examined. Medical treatment is undertaken at six principal clinics and subsidiary clinics have been installed in 12 schools. Dr. Roberts pronounces this last arrangement unsatisfactory.

Torquay.

The opening of an up-to-date open-air school at Homelands was the conspicuous feature of the year. This school, consisting of an admistrative block, a rest hut, and two open-air class-rooms, has accommodation for 60 children suffering mainly from general debility, many of them with a tuberculous tendency. Dr. T. Dunlop reports that the difference in the children's physique and mentality after a short attendance is remarkable; they lose their listlessness and apathy altogether, and there is an appreciable change in their mental state. The children arrive at the school at 9 o'clock and have three good meals a day. The provision of orthopædic treatment and advice is a problem to be tackled. At present the only way of dealing with these children is to send them to London or to one of the large provincial hospitals. The expense involved is great, and many of the parents are unable to afford even a fraction of the cost. An attempt has been made to get a decision from the Board of Education as to the authority's power to pay the whole or part of the cost. The Board's reply that the circumstances of each case must be submitted to them with an estimate of probable expenditure is not calculated to accelerate matters. 1317 children underwent routine examination and 36 per cent. of parents were present. Dental defects excluded, one child in four was found to be defective, and one in six was referred for treatment. 2·3 per cent. were suffering from malnutrition, 51·9 per cent. had dental decay, 6·8 per cent. having more than five teeth defective. Nine cases of tuberculosis were discovered, two of these being of the pulmonary variety.

VITAL STATISTICS OF ENGLAND AND WALES.

Birth-rate, Death-rate, and Infant Mortality during the First Quarter of 1921.

THE provisional figures of births registered during the first quarter of 1921 show a decline of over 61,000 from the record of the corresponding period of last year. Compared with the first quarter of 1914, however, the drop in numbers is under 8000. Excluding the war years, the births are the fewest recorded in the first quarter of any year since 1872. The provisional rate per 1000 living is, with the exception of the war years 1916–19, the lowest ever recorded for any first quarter.

The deaths registered also show a decline in numbers from the very low record of 1920, and are, indeed, the smallest in number registered in the first quarter of any year since 1868. The provisional rate is the lowest ever recorded for any first quarter.

The natural increase by excess of births over deaths was over 80,000 as compared with 133,000 in the March quarter of 1920, and 73,000 in 1914.

The infant mortality was 101 per 1000 births.

URBAN VITAL STATISTICS.

(Week ended April 23rd, 1921.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate population estimated at 18½ million persons; the annual rate of mortality, which had been 13·0, 12·5, and 12·5 in the three preceding weeks, was again 12·5 per 1000. In London, with a population of 4½ million persons, the death-rate was 12·6, or 0·2 per 1000 above that recorded in the previous week, while among the remaining towns the rates ranged from 5·0 in Wimbledon, 6·1 in Oxford, and 6·4 in Southampton, to 18·3 in Wakefield, 18·5 in Grimsby, and 20·7 in Warrington. The principal epidemic diseases caused 235 deaths, which corresponded to an annual rate of 0·7 per 1000, and comprised 68 from infantile diarrhœa, 61 from diphtheria, 50 from whooping-cough, 40 from measles, 15 from scarlet fever, and 1 from enteric fever. Whooping-cough caused a death-rate of 1·1 in Oldham, 1·5 in St. Helens, and 1·7 in Wigan. There were 3307 cases of scarlet fever and 2564 of diphtheria under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 3345 and 2543 respectively at the end of the previous week. During the week ended April 16th 3 cases of encephalitis lethargica were notified in the County of London, and comprised 2 in Southwark and 1 in Fulham. The causes of 31 of the 4441 deaths in the 96 towns were uncertified, of which 6 were registered in Birmingham, and 3 each in Stoke-on-Trent, Liverpool, and South Shields.

Scottish Towns.—In the 16 largest Scottish towns, with an aggregate population estimated at nearly 2½ million persons, the annual rate of mortality, which had been 15·5, 15·1, and 14·6 in the three preceding weeks, was again 14·6 per 1000. The 327 deaths in Glasgow corresponded to an annual rate of 15·5 per 1000, and included 27 from whooping-cough, 6 from infantile diarrhœa, 3 from diphtheria, and 1 each from measles and scarlet fever. The 138 deaths in Edinburgh were equal to a rate of 16·1 per 1000, and included 5 from measles, 2 from whooping-cough, and 1 from scarlet fever.

Irish Towns.—The 149 deaths in Dublin corresponded to an annual rate of 18·4, or 2·4 per 1000 above that recorded in the previous week, and included 6 from infantile diarrhœa. The 144 deaths in Belfast were equal to a rate of 17·9 per 1000, and included 8 from whooping-cough, 6 from infantile diarrhœa, 2 each from measles, scarlet fever, and diphtheria, and 1 from enteric fever.

VITAL STATISTICS OF LONDON
DURING MARCH, 1921.

IN the accompanying table will be found summarised statistics relating to sickness and mortality in the City of London and in each of the metropolitan boroughs. With regard to the notified cases of infectious diseases, it appears that the number of persons reported to be suffering from one or other of the ten diseases notified in the table was equal to an annual rate of 9·6 per 1000 of the population, estimated at 4,531,971 persons in the middle of 1920; in the three preceding months the rates had been

* Including membranous croup.

11·9, 10·4, and 10·0 per 1000. Among the metropolitan boroughs the lowest rates from these diseases were recorded in Kensington, Chelsea, the City of Westminster, St. Marylebone, the City of London, and Lambeth; and the highest in Hammersmith, Finsbury, Shoreditch, Bethnal Green, Poplar, and Woolwich. The prevalence of scarlet fever was about equal to that in the preceding month; this disease was proportionally most prevalent in Hammersmith, Bethnal Green, Stepney, Poplar, Bermondsey, and Woolwich. The Metropolitan Asylums Hospitals contained 3487 scarlet fever patients at the end of the month, against 4729, 4112, and 3799 at the end of the three preceding months; the weekly admissions averaged 469, against 590, 489, and 464 in the three preceding months. Diphtheria was somewhat less prevalent—about 10 per cent.—than in the preceding month; the greatest proportional prevalence of this disease was recorded in Hampstead, Islington, Stoke Newington, Holborn, Finsbury, Bethnal Green, and Greenwich. The number of diphtheria patients under treatment in the Metropolitan Asylums Hospitals, which had been 2615, 2648, and 2766 at the end of the three preceding months, numbered 2652 at the end of March; the weekly admissions averaged 290, against 316, 319, and 333 in the three preceding months. The prevalence of enteric fever was about equal to that in the preceding month; of the 17 cases notified during the five weeks ended April 2nd, 3 belonged to Finsbury, and 2 each to Paddington, Hampstead, Stepney, and Wandsworth. There were 10 cases of enteric fever under treatment in the Metropolitan Asylums Hospitals at the end of the month, against 15, 11, and 9 at the end of the three preceding months; the weekly admissions averaged 3, against 2, 3, and 2 in the three preceding months. Erysipelas was proportionally most prevalent in Paddington, Fulham, the City of Westminster, Hackney, Shoreditch, and Southwark. The 33 cases of puerperal fever included 4 in Paddington, 4 in Lambeth, 3 in Fulham, 3 in Wandsworth, and 3 in Woolwich. The 14 cases of cerebro-spinal meningitis included 2 in Finsbury, 2 in Shoreditch, and 2 in Deptford; while the case of poliomyelitis belonged to Wandsworth.

The mortality statistics in the table relate to the deaths of civilians actually belonging to the several boroughs, the deaths occurring in institutions having been distributed among the boroughs in which the deceased persons had previously resided. During the five weeks ended April 2nd the deaths of 5889 London residents were registered, equal to an annual rate of 13·6 per 1000; in the three preceding months the rates had been 14·2, 12·5, and 14·0 per 1000. The death-rates ranged from 10·6 in Deptford, 10·8 in the City of London, 11·1 in Wandsworth, 11·2 in Woolwich, 11·6 in Bermondsey, and 11·9 in Lewisham, to 15·4 in Islington and in Greenwich, 15·8 in Southwark, 16·6 in Kensington and in Holborn, and 16·7 in Finsbury. The 5889 deaths from all causes included 294 deaths which were referred to the principal infectious diseases; of these, 13 resulted from measles, 30 from scarlet fever, 103 from diphtheria, 49 from whooping-cough, 5 from enteric fever, and 94 from diarrhœa and enteritis under 2 years of age. No death from any of these diseases was recorded in Chelsea, Holborn, or the City of London. Among the metropolitan boroughs the lowest death-rates from these diseases were recorded in Hackney, Lambeth, and Deptford, and the highest in Paddington, Kensington, Fulham, Shoreditch, Bethnal Green, and Bermondsey. The 13 deaths from measles were only one-seventeenth of the average number in the corresponding period of the five preceding years; of these 4 belonged to Islington, 2 to Hackney, and 2 to Stepney. The 30 fatal cases of scarlet fever exceeded the average by 15; of these 4 belonged to Stepney and 3 to each of the boroughs of Fulham, Wandsworth, Camberwell, and Greenwich. The 103 deaths from diphtheria were 16 in excess of the average; the greatest proportional mortality from this disease occurred in Fulham, Hampstead, Islington, Stoke Newington, Shoreditch, Bethnal Green, and Bermondsey. The 49 fatal cases of whooping-cough were less than a third of the average number; of these, 8 belonged to St. Pancras, 7 to Islington, 6 to Kensington, 5 to Shoreditch, and 3 to Woolwich. Five deaths from enteric fever were registered during the month, against an average of 6; these deaths belonged respectively to the boroughs of Bethnal Green, Stepney, Bermondsey, Wandsworth, and Camberwell. The 94 fatal cases of diarrhœa were 22 in excess of the average number; the greatest proportional mortality from this disease occurred in Paddington, Kensington, Hammersmith, St. Marylebone, Bethnal Green, and Woolwich. In conclusion, it may be stated that the aggregate mortality in London during March from these principal infectious diseases was 48 per cent. below the average in the corresponding period of the five preceding years.

THE QUESTION OF A TRADE-UNION IN MEDICINE.

To the Editor of THE LANCET.

SIR,—Your leading article of April 23rd on the trade-union as a factor in medical politics does scant justice to some thousands of medical men who have agreed to combine in this form of organisation. It also conveys a direct challenge to them to give reasons for the faith that is in them. This would be easy were it not that one must appeal to an audience very largely uninformed as to the nature of a trade-union, and consequently prone to believe that strikes and commotions are of its very essence, the truth being that if strikes were rendered illegal to-morrow trade-unions would remain. You are no doubt aware that if two or three persons agree together on any course of action (not necessarily a strike) whereby some other person might find his business interfered with, that other person can proceed against them for conspiracy in restraint of trade. It is not necessary that the conspiracy should be in any way aimed against him or his business, or that the "conspirators" should be in his employ. The particular case prior to the Trade Union Acts was commonly that of a body of workmen agreeing together to ask for an increase of pay. It was not even necessary that they should threaten to stop work. So long as their request could be argued to operate in restraint of trade (as any demand for extra wages might well do) the conspiracy existed, and remedy could be had against them under the Common Law. Nor were the courts for many hundreds of years at all apt to exhibit any particular sympathy with the workmen. In these circumstances the State eventually interfered and legalised combinations of masters or workmen which had for their objects the improvement of the economic condition of either party. The State has never legalised combinations in restraint of trade which had other—e.g., political—objects. There can be no doubt in the minds of reasonable men that the State did right in this matter and that the first Trade Union Act was fully justified and was followed by an amelioration of the lot of the working classes which had long been overdue.

A later Trade Union Act did nothing to alter the nature of trade-unions, but it did legalise "peaceful picketing." That this was a mistake may well be argued, and I should certainly not be concerned to oppose this view. The fact remains that except by registration under the Trade Union Acts immunity cannot be obtained for any concerted attempt to raise wages. So long as the medical profession remained almost entirely individualistic there was no need of combinations to raise wages and the B.M.A. was naturally registered under the comparatively unrestricted form of a limited company rather than under that of a trade-union. At this time and for long afterwards the position of the B.M.A. was unchallenged. But times changed. A great part of the profession became State servants in whole or in part. The B.M.A. began to press for standard rates of wages and its right to do so was challenged, notably at Coventry. The result was profoundly disquieting. Large damages were given against the Association and the "warning notice," which was an essential part of the armament of the Association, had to be very much altered. It still remains, no longer a weapon but rather a weak spot in the armour of the profession. Fortunately the direct point of conspiracy in restraint of trade was not raised by the Coventry case or the result might have been far more damaging. There remained no doubt in the minds of those who had studied the subject that the activities of the Association and thereby of the profession were, and must be, seriously hampered by this difficulty about actions which might be held to be in restraint of trade. The Association considered that the best way out would be a trust fund able to operate in close touch with the Association but legally distinct from it. This fund has not had any very great measure of success, probably from doubts as to whether it was legally distinct. Certain members of the Association, on the other hand, thought that it would be better to register a separate body under the Trade Union Acts. It was hoped that the Association would coöperate with this body as far as it legally might. This hope was in vain and the Association embarked on a course of calculated hostility, its secretary freely making such remarks as that those who joined a trade-union had more money than sense. One may perhaps venture the further hope that the logic of events will eventually force an entente, not, however, of the nature of that subsisting between Jonah and the whale.

Your leading article affects to consider it impossible that medical men could ever contemplate a refusal of service because this would mean a refusal of treatment. May I cite a case which should, I think, convince you. There recently arose a vacancy in the post of medical officer to the Post Office in Gravesend. The terms offered not being satisfactory, the local practitioners intimated to the authorities that they had agreed together not to apply until the terms were altered. Very soon satisfactory terms were offered. This was a combined refusal of service, but it did not involve any refusal to treat the sick, and it may be doubted whether the sick were ever aware of it. Similarly, the whole body of insurance practitioners might refuse to comply with some particular regulation—e.g., the keeping of record cards. This would be refusal of service, but the sick would still be treated. It seems to have escaped your notice that there have been a great number of local refusals of service of recent years. A strike against one's patients is not thinkable in the present state of affairs, and one may hope that it never will be in this country. Yet our Austrian colleagues—not less humane than ourselves—were forced even to that extremity by the treatment to which they were subjected under the regime of Bela Kun. Necessity is the mother of more than invention, amongst other things of strikes and lock-outs. At present the necessity has not arisen, and there has been no general strike of medical men. But medical men as a whole are not particularly docile or easy to fool, nor do they lack a class consciousness. In all of which one may legitimately see possibilities of combined action on a scale undreamt of now so soon as the pressure of bureaucracy becomes sufficiently intolerable and not before. Action and reaction are equal and opposite. It is idle to suppose that the sphere of medical politics is exempt from general laws, or that the profession are so untutored that they cannot arrange an adequate reaction without ill-treating the sick.

It is not doubted by anyone that the editors of the *British Medical Journal* and of *The Lancet* are primarily actuated by a desire for the welfare of the profession and the progress of medical science. If they would but study that part of our industrial history which has witnessed the demand for and the growth of trade-unions, they might credit medical trade-unionists with motives not less worthy than their own and with at least as much knowledge of the possibilities of the bodies to which they belong. Tilting at windmills does no great harm to the mill, but it leads to involuntary antics which do little credit to the profession as a whole. And prejudice makes a poor weapon.

I am, Sir, yours faithfully,
GORDON WARD.

Sevenoaks, April 24th, 1921.

To the Editor of THE LANCET.

SIR,—It was a happy thought to turn the attention of your readers to the question of a trade-union in medicine. If the history of the last 60 years has taught us anything, it is that contract work engenders trade-unionism. You very rightly say that medicine is not a homogeneous service in which common conditions exist for all workers. In this statement you give the reason why the older Association has failed, and cannot but fail to conserve the interests of those who labour under a contract system. The "Medico-Political Union" is the outcome of this system. You ask in what manner could any medical strike be directed against the Government unless it was primarily directed against the sick and suffering. Is this a serious question? When we had some years ago the Battle of the Clubs, in which THE LANCET played so large a part, did the question of penalising the sick and suffering ever arise? When advertisements asking for sweated medical labour were refused insertion in the medical press did the managers lay themselves open to the charge of inhumanity? Has any medical trade-unionist ever suggested a strike against the sick and suffering?

Is that language accurate which describes a strike against the Ministry of Health as a strike against the Government? Do you wish to imply that medical trade-unionists are potential anarchists? When the profession in 1911 refused service under the proffered capitation fee of 4*s.* was it suggested that we struck against the Government? Week after week the medical press gives examples, not only of the dishonesty, but of the stupidity and impracticability of the regulations, but does one strike against the Government if one plainly says so? Our quarrel is not with the sick and suffering, but rather on their behalf. These regulations are framed by men who have no knowledge of panel work or of local conditions. Once start rules and regulations and you begin a vicious circle. Officials and regulations multiply until the sick and suffering can receive only a small part of the practitioner's attention. I am, Sir, yours faithfully,

Exeter, April 24th, 1921. J. PEREIRA GRAY.

GENERALIA ON THE LOUSE PROBLEM ON THE WESTERN FRONT.

To the Editor of THE LANCET.

SIR,—Mr. A. D. Peacock's article under this heading, which appeared in your issue of March 26th, calls for comment in several particulars. As I was Sanitary Officer to the Second Army, in which Mr. Peacock also served, I trust I may be allowed to bring the following remarks to notice. Mr. Peacock's article is very properly termed "generalia," and sketching, as it does, so many points, does not admit of a completely "laid-out" reply. He treats of certain facts and offers divers opinions and criticisms.

With regard to his facts as to the proportion of men infested with lice, I can speak only of front line troops, and I would like him to know that the army medical authorities always exercised a much simpler and more direct method of ascertaining the amount of infestation than he appears to have employed. This was by making direct inquiry from regimental medical officers and from officers in charge of medical units receiving sick and wounded men the amount and degree of prevailing infestation. I can think of no better method.

As to the means at our disposal for disinfestation in the field, the list furnished by Mr. Peacock on p. 637 under the heading "Comparison of Types of Disinfestor" presents a picture which is *not only* incomplete and historically inaccurate, it is so much out of perspective as to be distorted. Under the heading "Apparatus" he mentions six types in all, three of these being "steam" and the remainder "hot-air." In general, the list of apparatus mentioned fails altogether to give the relative capacities and use of each type named, likewise the length of use and date of introduction of each type is omitted. The uninitiated, I fear, might fail to gather from Mr. Peacock's list the important fact that in so far as the Second Army was concerned—from the date of its formation in 1914 until its departure for Italy in November, 1917—none of the hot-air types of disinfestor was in use. From inquiry I have made as to the period between December, 1917, and the signing of the armistice in 1918, but few experimental types of hot-air disinfestors had been erected on the Western front. Certainly, in 1919, I saw none in Italy, and none in North Russia on the Murmansk front, where our troops came in close contact with cases of typhus and small-pox amongst the civil population.

Experimental work on disinfestation carried out under laboratory conditions may be highly successful, given certain desiderata, and this applies to hot-air as to other types of disinfestor. It would be interesting to hear from Mr. Peacock how he overcame certain objections to hot-air disinfestation formulated by him in a report he furnished to the Second Army medical authorities. In that report Mr. Peacock stated that in his opinion, as the result of experimental work carried out in the Second Army, the objections to the use of hot-air disinfestation were as follows: (1) Danger from fire; (2) the impracticability of raising the temperature of the walls and floor of the disinfestation chamber to the required degree; (3) the method failed when dealing with wet and muddy garments; (4) the low penetrating power of hot air.

Mr. Peacock's picture is incomplete because of the lack of reference to the use of the Clayton apparatus in which SO_2, admixed with a small percentage of SO_3, is generated as the disinfesting agent, the gases being made to circulate continuously in the disinfestation chamber as required, while the percentage of gases is under the control of the operator. One of these machines was provided for the use of each corps from the middle of 1915 onwards, and, in addition, there were fixed installations at other centres. No history of disinfestation is complete without mention of these machines, which, in addition to their prolonged use on the Western front—as, indeed, they were on all other fronts—are officially approved by the French Government. The British War Office also considered these machines of sufficient importance to warrant their inclusion in the D.G.M.S. Circular actually referred to by Mr. Peacock, and, in addition, some 10 pages are devoted to them in the official publication "Notes for Sanitary Officers of the British Expeditionary Force in France." In my opinion no type of disinfestor approaches the efficiency of the Clayton machine in dealing with verminous dwellings and their contents in situ. (In order that there may be no misconception, allow me to say that I have no interest in the Clayton apparatus whatever beyond its utility.)

My experience of the working of all types of disinfestor in the field was that when they failed to act the fault lay rather with the operator. The one outstanding exception was at the Laiterie, Poperinghe, where the construction of the steam chambers was at fault. Alterations on the lines laid down by Mr. W. A. Muirhead, chief sanitary inspector at headquarters, were carried out, and the installation became sufficiently successful as to serve as a model for other centres. Further, the local corps requirements were adequately met.

With regard to the opinions and criticisms offered by Mr. Peacock, these, collectively, give the impression that the medical officers on the Western front neither realised nor appreciated the importance of combating lousiness amongst the troops. Mr. Peacock states: "The discomfort of lousiness, its effect on men's sleep and rest, and the resulting depression of their physical fitness were never considered poignant reasons for disinfestation, while the more apparent effect of skin diseases, directly and indirectly traceable to lice (as well as the scabies mite), did not make sufficient appeal," and yet further on he writes the following: "The arrangements for the bathing of troops and the disinfestation and laundering of their underclothing in the front areas, though not adequate, were generally most creditable, but there still remained the great problem of the disinfestation of the outer clothing."

Mr. Peacock rather laments the fact that, despite all, his teachings and advice to officers in charge of combatant troops and to others, as the sequel showed, was merely giving "counsels of perfection." Is this not rather a confession of failure on the part of Mr. Peacock who had been given a free hand to conduct the necessary propaganda both at organised schools of instruction and elsewhere? Personally, I think Mr. Peacock has seriously under-estimated both the result and value of his labours in the direction of disinfestation. I think he will agree with the latter view when he learns that, despite the ever-increasing concentration of troops, there was little increase in lousiness. I would like him to realise the plain fact that in November, 1917, the Second Army had a ration strength of over 800,000 men, and was concentrated on a sinuous front having a diagonal measurement from north to south of only about 12½ miles! We have all appreciated Mr. Peacock's research work and efforts to combat lousiness in the field, and hope he is continuing his studies as a peace problem—for even as there are lousy soldiers, so are there lousy families and lousy households, which some of us consider as the "fons et origo" of the trouble.

Lastly, I respectfully suggest to Mr. Peacock, when next he feels inclined to indulge in melancholy mood and, peradventure, publishes further "Generalia" based on his individual views on the shortcomings of army authorities in the field, to bear in mind the significance of certain utterances made by another lay worker, Mr. Dan Jenkins, secretary of the Public Health Committee of the Labour Party, at a sectional meeting of the British Medical Association held last summer at Cambridge, who then stated: "The Labour Party desires for the working man and his family, at home, the same standard of medical organisation, skill, and care as was shown for the British armies in France. The Army Medical Service and the Royal Army Medical Corps have shown the way."

I am, Sir, yours faithfully,
M. COPLANS.

The Jenner Institute Laboratory, Church-road,
Battersea, S.W., April 20th, 1921.

SKIN REACTIONS IN TOXIC IDIOPATHIES.

To the Editor of THE LANCET.

SIR,—A number of colleagues, both laboratory and clinical, have been asking recently how one prepares the testing substance for skin reactions in diagnosis of asthma, eczema, urticaria, food idiosyncrasies, and so on. This shows that no one has been explicit enough in describing methods, and also that there is a demand for such information. I will give here without going into details some simple practical directions.

The test substances (which I should like to call "idiopathophanes"—meaning that which demonstrates an idiopathy) may be prepared in a number of ways as follows:—

1. *The crude substance direct* can generally be employed without any preparation; for example, any of the flours (such as barley or wheat), or white of egg, or the hairs of an animal (for an animal asthmatic), or even such things as uncooked meat or vegetables. There are three disadvantages: The substance may give too strong a reaction, as, for example, grass pollen for diagnosis of hay fever; secondly, the substance may contain a strong acid in certain (e.g., fruit juices), which may react of its own accord quite apart from the proteid contained; thirdly, it is not very convenient to keep all the year round in the consulting-room a supply of, for example, pork or onions or strawberries.

2. *Desiccated preparations* are sometimes convenient; for example, desiccated white of egg or a desiccated serum will keep indefinitely, and may be conveniently stored in small bottles.

3. *The proteids may be extracted.* The literature on the subject is full of demands that these proteids should be chemically pure, and then usually goes on to describe a method which could not possibly produce pure preparations. In practice I find that alcoholic precipitates from a watery solution work well, but are frequently difficult to collect and keep.

4. *Test paper preparations* can be made from the precipitates of No. 3 by filtering the 10 per cent. of water and 90 per cent. of alcohol containing the precipitate through filter paper over a vacuum. These impregnated filter papers can be kept dry in envelopes arranged on a card index system. Undoubtedly this is the handiest method of storage, and is the one I employ in general. These idiopathophanes keep well; I am now using some I made over two years ago.

5. *Graduated dilutions* of a watery extract must be employed if patients react too powerfully to the undiluted substance. This is so with hay-fever people, for application of the dry pollen of grasses may produce not only a local reaction but also violent constitutional disturbances, asthma, œdema, swelling up of the glottis, &c. Suitable dilutions of the watery extract (1 part of pollen in 200 water, down to 1 part of pollen in 200,000 of water) have been put on the market for testing purposes by Messrs. Parke, Davis, and Co. for many years. Such graduated dilutions must, of course, be used if any quantitative estimate of the sensitiveness is to be made.

6. *Autolysed cultures of bacteria* (e.g., from cases of bronchial asthma), after sterilising by filtration, can either be used directly or precipitated by alcohol and used as in No. 4.

The skin reactions are made by rubbing some preparation of the suspected material on to a scratched surface of skin. These scratches may be made anywhere, but the forearm, or just above the knee, are convenient sites. Reactions are judged from urticaria at the site of the scratches and from surrounding erythema. With a new patient a control scratching with only water placed on it should always be made; and with a new test substance a control scratching should always be made on a normal man—e.g., the practitioner.

I am, Sir, yours faithfully,

Devonshire-place, W., April 20th, 1921. J. FREEMAN.

CONGENITAL WORD-BLINDNESS.

To the Editor of THE LANCET.

SIR,—In your issue of April 23rd you give on p. 890 a paper by Dr. Wallace Wallin on this subject which is of great interest. I wish he had paid more attention to the question of inheritance, which was first dealt with by Mr. Sydney Stephenson, for to my mind this line of investigation will lead to a better understanding of the disease. A striking thing about Dr. Wallin's paper is the close similarity between his figures of incidence and those of colour-blindness, and also the fact that the sex-incidence is the same. This similarity of incidence would suggest strongly that it is hereditary, and it would be informing to follow cases to see if the method of transmission in word-blindness follows the same course as that of colour-blindness. There is one significant thing which I have noticed in two cases of partial word-blindness, and it is that both subjects were above normal at figures.

I am, Sir, yours faithfully,

Rugby, April 24th, 1921. ARTHUR WOOD.

THE DIET OF THE WEANLING.

To the Editor of THE LANCET.

SIR,—The annotation in your last issue on the diet of the weanling will be of great service if it stimulates interest and inquiry into the special difficulties at this period of life. You rightly point out the lack of sound principles by which the prescription of food can be regulated. Until these principles are outlined and agreed upon the diet will continue to be directed by rules which too often express the idiosyncrasies of the physician or obediently conform to some tradition or school and escape critical examination for that reason. The infant at this age shows again and again how much its survival owes to the versatility of its digestion. Nevertheless there must be rules, could we but find them, which might spare the strain under which even this versatility so often breaks down. As you quoted a suggestion of mine that the young child may not be so dependent on cow's milk for its health and physical development as is commonly thought to be the case, I should be glad if you would allow me to explain a little more fully what the suggestion implied. For it is, I believe, quite closely concerned with one of the principles of dietetics whose existence it is so important to get defined.

It is a common recommendation by doctors that during the second year of life a child requires from a pint and a half to two pints of milk daily. Inasmuch as it is practically impossible for a yearling to assimilate more nourishment than two pints of milk afford, this order implies that milk-feeding is still *the* essential feature of diet at this age. It is impossible also to escape the implication that the cow is really performing the function of foster-mother, and is continuing to the eighteenth or twenty-fourth month the task which the mother is usually told she should abandon about the ninth month. It is no good doctors saying they do not mean this or anything like it when they recommend a diet chiefly of milk. The denial merely means they have never thought about what they are ordering. To say cow's milk is a convenient way of giving water to a child is about as rational as to say whisky is a convenient vehicle for prescribing soda-water. Until Mr. Ford has realised his ingenious idea of providing a mechanical cow, milk remains what it always has been—the food of the young mammal from birth until the age when it can digest the diet of the adult. That cow's milk forms an ingenious addition to our sources of fat and protein is an aspect of its utility quite separate from the point at issue. The question here is to decide when does the normal infant reach the stage at which milk-feeding stops? Has the human mother so far lost the power of lactation that she can only perform half her task, and that the cow must finish it for her? Or has something befallen our babies that nowadays, after their mothers have done all that can be done in the way of breast-nursing, they need an extra 12 or 15 months' milk diet before they reach digestive independence? To many these questions may sound merely a quibble. It can be argued that milk is a valuable food, easy to procure and convenient to give. On the other hand, we must recollect that, whereas an adult can frequently select or modify his diet as his inclinations prompt, a yearling has virtually no choice in the matter. He has, at any rate, to fight for a pathetically long time before his dislikes are admitted to have a physiological foundaton.

There are many reasons for supposing the child's development undergoes changes which correspond very accurately with the adoption of a solid in place of a fluid diet. The appearance of teeth, the slowed and altered character of growth, coincide with a marked change in habits. The previously placid creature, mainly content to sleep and feed, becomes an energetic acrobat who takes an immense amount of physical exercise. There is, further, the interesting fact, often attributed to obstinacy or original sin, that about this age he stoutly refuses to be fed entirely on milk, and shows an almost unconquerable preference for solid food. Another piece of evidence, which your annotator considers unprofitable, but which I still think may carry conviction, is to be found in the very perfect physique of large numbers of children to be seen playing in the streets of this city, who have been reared on the primitive plan I have suggested may be the normal. They have in many cases been nursed entirely at the breast for six or seven months. After that small amounts of solid food were allowed, and a steady substitution by their parents' meals for the breast milk has gone on up to the age of about 15 months. From that age milk, except in the preparation of food, ceased to be included in their diet; water was their drink. The parents, if patiently questioned, will reveal this manner of rearing their children, but with considerable misgiving if the questioner be a doctor, nurse, or official of any sort. For they have learned that their plan runs directly counter to medical approval, though they retain a shrewd feeling that their results justify their method. It may surely be well worth our while to inquire whether these parents have preserved many hints on diet, handed down by precept and word of mouth, which contain physiological and biological truth of great value. Obviously the method just outlined is open to abuse. But one fact has impressed me about its application—children who have developed well in their first months are very easily fed by this method, and the process of weaning is achieved very smoothly.

To suggest that this is approximately the normal method is not to deny the value of cow's milk for many infants—dirty a food as it unfortunately still is in this country. It can, with proper precautions as to cleanliness and modification, very conveniently replace the mother's milk during the later months. But the amount given I believe need seldom exceed 10 or 15 oz. per diem for the normal child, and requires to be steadily diminished if the full ration of solid food is allowed. In cases of delicacy or illness the value in much larger amounts is often, of course, unquestionable long after the age at which it would normally have been given up. But it must be a common experience to see children—and this is a final piece of evidence which I believe your annotator will accept—whose development is thwarted and disordered simply by virtue of having been fed excessively on cow's milk. Once admit the rationality of these children's dislike for their diet, allow them to satisfy their thirst with water and share their parents' food, and their nutrition tends to swing back towards the normal at a rate which is often surprising. Provided—and it is a most important proviso—that their parents choose food of a suitable kind and prepare it in a suitable manner. Exactly what food and what amount should be given is, of course, another aspect of the subject altogether, full of its own difficulties. But my contention is that we have been greatly handicapped in our search for a suitable diet by the unnatural incubus which pints of cow's milk place on infantile digestion.

I am, Sir, yours faithfully,
HAROLD WALLER.

Cheyne Gardens, Chelsea, S.W., April 25th, 1921.

To the Editor of THE LANCET.

SIR,—Your annotation on the Diet of the Weanling seems a very fair summary of the position of our present knowledge of the subject. May I refer to some points in it? "Proper development of mouth and jaw" and "nasal breathing" are surely promoted by good use of all the muscles of mastication. Further, that the mechanical and chemical nature of the food is a very important factor in dental caries is certainly accepted by Sir Frank Colyer in his chapter on the subject in the last edition of Dental Pathology.

As to habits acquired in the nursery—though the infant in first attacking his crust swallows most in a finely divided form—he necessarily has to reject a few large pieces which come off in his mouth. This is to be encouraged rather than that he should learn to bolt it and is a necessary and unsightly stage in the process of his education. The stage does not last long we find. Personally, from an æsthetic point of view, I prefer to sit at table with a child of, say, 2 years old, who crunches a piece of hard toast with appetite rather than with one who passively and absent-mindedly allows a nurse to poke slop food into his open mouth. The first child is learning self-reliance, is a pleasanter table companion, and almost invariably has a better digestion than the one who passively allows the nurse or mother to feed him and to substitute other fluids for his salivary secretion.

I am, Sir, yours faithfully,
MARION COCKERELL,
Medical Officer, Argyle-square Infant Welfare.
Letchworth, April 26th, 1921.

SEPARATION OF BACTERIA BY ALKALI SOLUBILITY.

To the Editor of THE LANCET.

SIR,—In reference to the articles by Dr. David Thomson on the Biochemistry of Germs, in your issues of April 16th and 23rd, I think it might interest him to know that various bacteria are not only soluble in different strengths of alkali, but can be separated in a living state by this means. The technique, which has been elaborated by Mr. W. J. Matthews, the assistant at the pathological department of the Bristol Royal Infirmary, for the rapid separation of organisms in the preparation of vaccines is, without entering into minutiæ, as follows:—

> All Gram-negative organisms may be removed by decinormal NaOH. The treatment of the deposit of bacteria left after centrifuging with normal NaOH will kill all the commonly found Gram-positive saprophytes and leave streptococci and staphylococci alive. These can be separated by still stronger alkali, the staphylococci being the more resistant.
>
> By employing different strengths of alkali combined with subsequent growth in selective media rapid separations of bacteria can be effected and pure cultures obtained within 24 hours. Acids can be similarly employed, but are not as useful.

These devices were suggested by the preparation of detoxicated vaccines as described by Dr. Thomson, and have saved much time and trouble during the last year. Dr. Thomson believes the bacterial proteins to be similar to animal proteins. My observations lead me to believe that they differ much from both animal and vegetable proteins; for example, the alkaline solutions scarcely yield a biuret reaction.

I am, Sir, yours faithfully,
Clifton, Bristol, April 26th, 1921. J. R. KAY-MOUAT.

JERUSALEM UNIVERSITY LIBRARY.

To the Editor of THE LANCET.

SIR,—At the Third Annual Conference of the Inter-University Jewish Federation, held at Oriel College, Oxford, on August 3rd, 1920, it was unanimously resolved, in response to a request of the Zionist Organisation, to render every possible assistance to all efforts on behalf of the Hebrew University at Jerusalem. The most urgent need at the present juncture is an immediate and abundant supply of books for the Jerusalem University Library. We can conceive no cause more precious and commendable than the full development and firm consolidation of the intellectual and spiritual resources of the Jewish National Home. To this end books are the first requisite. In a scarcity of books the mind of a people is denied free expansion and healthy growth. To Jews with their love of learning the want of books is most distressing. In Palestine, unfortunately, there is a real book famine, and even with help from all over the world it will need a great effort to build up the present University library of about 40,000 volumes into an up-to-date library worthy of the Jewish University.

Serious works dealing with all branches of knowledge, standard works of fiction in any language, and more especially books which will be of use to university students are needed. Books on Hebraica, Judaica, and Semitica, mathematics, physics, chemistry, microbiology, and medical research are, however, the most urgently called for, as the first departments of the University that are to be opened will deal in research in these subjects. Books on law, economics, history, and philosophy will also be much appreciated. Sets of scientific journals, transactions of learned societies, official reports, and other publications and works and pamphlets of permanent value are especially required; good text-books of established repute will also be useful.

Considering that this is an important step towards a spiritual revival of Palestine and that our credit as an enlightened people is at stake, we appeal to your readers to send all the books they can spare as a free-will offering to those who will treasure them in Palestine. A single book will be welcome; but it is hoped that donors will send as many as they can. Gifts of books may be sent either direct to "The University Library, Jerusalem," or to the hon. secretary, Mr. D. B. Stanhill, B.Sc., F.I.C., 75, Great Russell-street, London, W.C. 1, who will, if necessary, arrange for the collection of the books. An artistically designed book-plate, the generous work of Mrs. L. Pilichowski (Lena Pillico) will permanently record the names of the donors.

We are, Sir, yours faithfully,
S. ALEXANDER, Chairman.
ISRAEL M. SIEFF, Treasurer.
D. B. STANHILL, Hon. Secretary.
April 21st, 1921. HARRY DAGUT, Chairman, I.U.J.F.

VENEREAL INFECTION IN RHINE ARMY.

To the Editor of THE LANCET.

SIR,—With further reference to my letters[1] giving the American rate for January–October, 1920, as 142 per 1000 per annum, and for November 1920–April, 1921, as 114 per 1000 per annum, I now learn that the American rate has been still further reduced, the latest available figures being as follows:—

	Per 1000 p.a.
Week ending April 1st	76·26
,, ,, ,, 8th	79·74

We are still without any better figures for the British Forces on the Rhine than those quoted recently in Parliament—viz., 168 per 1000 per annum—more than twice the present American rate.

As the question of issuing directions with medicaments is now under official consideration in England I quote the following from a recent American Army report:—

"The use of ointment or cream as a protective and lubricant before intercourse has been insisted upon by us for some time. *The printed directions which are securely pasted to the container in which all individual prophylactics are issued are specific on this point.* It is without doubt a preventive measure of great value. The principle has been made use of by mechanics in the preliminary preparation of their hands with soap before work. The soap fills the pores of the skin, thus preventing grease and dirt from penetrating, while subsequent cleansing is greatly facilitated. Our chief difficulty lies in getting men to use prophylaxis (either personal or at stations), and this in spite of the fact that all men who acquire venereal disease without having taken prophylaxis at stations are brought before courts martial."

This also was the chief difficulty with the Anzacs, but we overcame it very largely (1) by personal appeals for cleanliness for the sake of the women and children at home; and (2) by recommending disinfection with absolute confidence, and attributing failures not to the medicaments but to careless application—the individual responsibility of the man who incurred the risk of disease.

I am, Sir, yours faithfully,
ETTIE A. ROUT,
April 26th, 1921. Late Hon. Sec., N.Z. Volunteer Sisters.

HYPNO-NARCOSIS.

To the Editor of THE LANCET.

SIR,—In your interesting leading article in THE LANCET of April 16th on Professor Friedländer's hypno-narcosis, you mention James Esdaile's work on surgical operations under mesmerism. I would ask you to permit me to make a few additional remarks with reference to the latter. Esdaile was a surgeon in the Indian Medical Service; he followed Thomas Wise[1] (another surgeon in that Service) as civil surgeon of Hooghly (near Calcutta) in 1839. He commenced operating under mesmerism on April 4th, 1845, at Hooghly, and in eight months he carried out 73 operations on patients, some of them being major operations, such as removal of scrotal tumours (one of which weighed 80 lb.), excision of the breast, amputations, &c. On receiving the record of these Government ordered a committee to report on further experiments carried out by Esdaile in the Calcutta Native Hospital. Of the first ten patients experimented on three could not be mesmerised; the other seven were mesmerised and operated on successfully, in four painlessly, in three the complete absence of pain was considered doubtful. The committee's report being favourable, the Government sanctioned the opening of a mesmeric hospital in Calcutta in November, 1846, for one year. Into this hospital all kinds of surgical cases were admitted for operation under mesmerism. It was closed in January, 1848. The public of Calcutta appealed to Government to keep the institution going; the reply given was that this could be done by voluntary subscription. It was reopened under Esdaile on Sept. 1st, 1848, but only for another year. Shortly after this Esdaile was appointed as superintendent of a large dispensary in Calcutta, and continued to practise mesmerism in it until June, 1851. I am indebted to Lieutenant-Colonel D. G. Crawford's delightful "History of the Indian Medical Service" for some of these facts.

The introduction of chloroform in 1847 by Sir James Simpson naturally militated against the widespread use of mesmerism to produce unconsciousness in operations. If Esdaile had worked a century earlier, or the discovery of general anæsthesia had been delayed for a few generations he, like Sir James Simpson, would have been enrolled among the immortals.

---

[1] THE LANCET, March 26th (p. 666) and April 16th (p. 825).

[1] Wise was the author of one of the best accounts we possess of Ayurvedic treatment, entitled Commentary on the Hindu System of Medicine, Calcutta, 1845.

Regarding Esdaile's work the late Mr. F. W. H. Myers[2] says:—

> "His success was absolutely unique; it was certainly (setting aside supernormal phenomena) the most extraordinary performance in mesmeric history. Had not his achievements been matters of official record the apparent impossibility of repeating them would probably by this time have been held to have disproved them altogether."

A further reference[3] to Esdaile's work states that he performed "upwards of 300 capital operations of every description, and many of them of the most terrible nature, without inflicting pain on the patients, and in every instance the insensibility was produced in this fashion."

The phenomena of hypnotism have long been known to almost all Oriental nations. The fakirs of India, the musicians of Persia, the priesthood of Egypt and Greece, the seers of Rome, the monastic recluses of the Middle Ages, and the ecstatics of the seventeenth and early eighteenth centuries, exhibited many symptoms attributed by religious enthusiasts to supernatural agencies, but explicable by what is now known of hypnotism. The Jogins, who appear to hibernate at will; the Dandins, who become cataleptoid by 12,000 repetitions of the sacred word "Om," might be instances of auto-hypnotism. Hue and Hedwald tell us of hypnosis in Buddhist monasteries and convents in Thibet, and Sperling speaks of the postures of dervishes at Constantinople as due to auto-hypnotism. Many strange stories are related of Indian fakirs; if the incidents described are not jugglers' tricks, they are possibly connected with self-induced hypnosis.

I am, Sir, yours faithfully,
P. HEHIR,
Major-General, I.M.S. (ret.).
April 16th, 1921.

ANTITYPHUS VACCINATION.

To the Editor of THE LANCET.

SIR,—I think it is of importance to correct an inexactitude in the article by my friends Dr. J. M. Mitchell and Dr. G. P. N. Richardson, dealing with the preparation of antityphus vaccine, in THE LANCET of April 9th (p. 742). I acquainted them with details of the preparation of vaccine which I used at the time when I was testing the result of the addition of carbolic acid: this addition was rejected, as *it produced, even in very small quantities* (*0'25 per cent.*) *secondary coagulation of blood* during inactivation. The addition of carbolic acid *after* inactivation was considered dangerous. The conditions under which the work was done were very unfavourable. There was no available laboratory: all instruments and apparatus were improvised from kitchen jars, wine bottles, &c., as it was impossible to obtain proper materials in Russia. The blood was inactivated in stoppered bottles completely immersed in water; superfluous opening for addition of any preservative was considered dangerous under the existing conditions of preparation. Moreover, in about 500 cases where injections were given during the epidemic of November and December, 1919, mentioned in the article, I observed no complication.

I am, Sir, yours faithfully,
Dr. I. N. ASHESHOV,
i/c of Government Bacteriological Laboratory,
Dubrovnik (Rugusa), Yugoslavia.
April 17th, 1921.

THE ANTENATAL CLINIC AND PLACENTA PRÆVIA.

To the Editor of THE LANCET.

SIR,—It will be distinctly advantageous when the antenatal clinic is advised and carried out by the medical profession as a routine practice in the case of every woman during the last month of pregnancy. By this means the following would be known beforehand:—

(1) Whether a natural labour may be expected.
(2) If all organs are working properly.
(3) Whether the pelvic measurements are normal.
(4) Whether labour is obstructed, and by what.
(5) The position of child and probable presentation.
(6) The site of the placenta.

If the placental souffle can be easily heard when the stethoscope is placed on the abdomen over the fundus uteri, all anxiety on this subject may cease, but if not heard the cervix must be investigated, when a thickened feeling will confirm the suspicion of the presence of the placenta. For the purpose of further investigating a solid wooden instrument has been made, consisting of a smaller end which is passed up to the os uteri, while to the larger end which projects a binaural stethoscope can be applied. Thus, through a good conductor is conveyed the sound of placental circulation, and if present, the diagnosis of placenta prævia may be considered certain and Cæsarean section called for.

I am, Sir, yours faithfully,
Deal, April 15th, 1921. THOMAS H. MORSE, F.R.C.S.

UNIVERSITY OF BIRMINGHAM: LECTURESHIP IN PSYCHOTHERAPY.

To the Editor of THE LANCET.

SIR,—May I correct an error that has crept into the announcement of the lectureship in Psychotherapy at Birmingham University in your advertisement columns of April 16th? I am there wrongly described as lecturer in *Psychotherapy* at King's College, whereas my position is the more humble one of lecturer in *Psychology*. The announcement has naturally given rise to some misapprehension. I am, Sir, yours faithfully,
Harley-street, W. April 17th, 1921. J. A. HADFIELD.

*** We make the correction gladly, adding that the wording of the advertisement was precisely as received from the University of Birmingham.—ED. L.

THE INFLUENCE OF AERATION ON THE ANTISCORBUTIC FACTOR.

To the Editor of THE LANCET.

SIR,—I have just noted the article by Dr. S. S. Zilva which you published in your issue of March 5th on this subject. I have thought that your readers might be interested in the fact that this is a confirmation of work which I reported before the meeting of the British Medical Association last summer, and of which the following is a short account. You will see that Dr. Zilva's work confirms mine.—I am, Sir, yours faithfully,
ALFRED F. HESS.
West 86th-street, New York, April 2nd, 1921.

[*Enclosure.*]

THE DESTRUCTIVE EFFECT OF OXIDATION ON ANTISCORBUTIC VITAMIN.[1]

BY ALFRED F. HESS AND LESTER J. UNGER.

[*From the Department of Pathology, College of Physicians and Surgeons, New York City.*]

As stated elsewhere (Hess, A. F.: Brit Med. Jour., 1920, ii., 147), the antiscorbutic vitamin is destroyed by oxidation. Such was found to be the case when 4 c.cm. of a normal solution of hydrogen peroxide were added to a litre of raw milk, which was then placed in the incubator overnight. Bacteria did not develop in the incubator under these conditions. When 80 c.cm. per capita of this milk was fed to guinea-pigs, in addition to oats, they all developed scurvy in about three to four weeks, a result similar to feeding experiments with milk which had been autoclaved for one hour at 120° C. The addition of orange juice to the dietary served either to protect or to cure animals on this dietary.

Orange juice subjected to oxygen for a short period was likewise found to have lost some of its potency. Previously we had found that milk or tomato juice which had been shaken had lost some of this vitamin. Probably this deleterious action is partly due to the effect of oxidation. The harmful effect of "ageing" may also be interpreted in this way.

As foodstuffs undergo oxidative processes frequently in the course of various manipulations, no doubt this factor plays an important rôle. This action probably explains the differences in the antiscorbutic potency of foodstuffs which have been treated in apparently similar ways, for example, of milk which has been heated in open pans or in hermetically sealed bottles.

The Services.

INDIAN MEDICAL SERVICE: CIVIL EMPLOYMENT PAY.

THE following communiqué has been received from the India Office:—

1. With effect from Jan. 1st, 1920, the new scales of pay for officers of the Indian Medical Service in civil employment are as follows:—

(a) The rates of pay for officers of the Indian Medical Service in civil employment, who hold one of the following appointments, are as specified below:—

Director-General, Indian Medical Service, Rs.3500.
Surgeons-General, Rs.3000.
Inspectors-General of Civil Hospitals, Rs.2750.
Sanitary Commissioner with the Government of India, Rs.2500, rising by annual increments of Rs.100 to Rs.3000.
Inspectors-General of Prisons, Rs.2300, rising by annual increments of Rs.50 to Rs.2500.
Sanitary Commissioners, Bengal, Bihar and Orissa, United Provinces, Punjab, Madras, Burma, Bombay and Central Provinces, Rs.2100, rising by annual increments of Rs.60 to Rs.2400.
Sanitary Commissioner, Assam, Rs.1950, rising by annual increments of Rs.50 to Rs.2300.
Principal, Medical College, Calcutta, Rs.2350.
Superintendent, Campbell Medical School, Calcutta, Rs.2350 for a Lieutenant-Colonel and Rs.1950 for a Major.
Senior Medical Officer, Port Blair, Rs.1950.
Surgeon Superintendent, Presidency General Hospital, Calcutta, Rs.2350.
Surgeon Superintendent, St. George's Hospital, Bombay, Rs. 2350.
Superintendent, General Hospital, Rangoon, Rs.2150.

(b) The rates of pay of officers of the Indian Medical Service in civil employment, who do not hold any of the appointments specified in the other clauses of this paragraph, are shown in the following statement:—

Rank and Service.	Pay.	Overseas pay.	Total pay.
	Rupees per month.		
Lieutenant	500	150	650
Captain—			
(i.) During the first 3 years' service as Captain	650	150	800
(ii.) With more than 3 and less than 6 years' service as Captain	750	200	950
(iii.) With more than 6 years' service as Captain	850	200	1050
Major—			
(i.) During the first 3 years' service as Major	950	250	1200
(ii.) With more than 3 and less than 6 years' service as Major	1100	250	1350
(iii.) With more than 6 years' service as Major	1250	250	1500
Lieutenant-Colonel—			
(i.) Until completion of 23 years total service	1500	250	1750
(ii.) During the 24th and 25th years' of service	1600	250	1850
(iii.) After completion of 25 years' total service	1700	250	1950
(iv.) When selected for increased pay ...	1850	250	2100

(c) The rates of pay in columns (3) and (5) of the statement in clause (b) are increased by Rs.250 a month for all officers of the Indian Medical Service who hold one of the following appointments: (1) Professorial appointments, Bengal, Punjab, United Provinces, Madras, and Bombay; (2) Principal, Lahore Medical College; (3) Principal, Lucknow Medical College; (4) Surgeon to Gokuldas Tejpal Hospital, Bombay; (5) Imperial Serologist; (6) appointments in the Bacteriological Department; (7) Chemical Examiners; (8) Deputy Sanitary Commissioners; (9) Port Health Officers at Bombay, Calcutta, Rangoon, and Aden; (10) Health Officers, Simla, Imperial Delhi, and Delhi Municipality; (11) Plague Medical Officers; (12) Deputy Director-General, Indian Medical Service; (13) Assistant Directors-General, Indian Medical Service (Sanitary), and (Stores); (14) Surgeon to His Excellency the Viceroy; (15) Police Surgeon, Rangoon; (16) Superintendents, Central Lunatic Asylums; (17) Superintendent, X Ray Institute; (18) Superintendent, Royal Botanical Gardens, Calcutta.

(d) The rates of pay in columns (3) and (5) of the statement in clause (b) are increased by Rs.200 a month for all officers of the Indian Medical Service who hold one of the following appointments: (1) First and Second Resident Surgeons, Presidency General Hospital, Calcutta; (2) Resident Surgeon, St. George's Hospital, Bombay; (3) Surgeons to Their Excellencies the Governors of Bombay, Madras, and Bengal.

(e) For Superintendents of 1st class Central Jails and the Second Medical Officer, Port Blair, the rates of pay in columns (3) and (5) of the statement in clause (b) are increased by Rs.150 a month.

(f) For personal assistants to Surgeons-General the rates of pay in columns (3) and (5) of the statement in clause (b) are increased by Rs.100 a month.

(g) For Superintendents, 2nd class Central Jails, the rates of pay in columns (3) and (5) of the statement in clause (b) are increased by Rs.50 a month.

(h) In addition to the above rates of pay officers of the Indian Medical Service who hold one of the following appointments draw in addition the duty allowances mentioned: (1) Officers of the Bacteriological Department who are directors of 1st class Central and Provincial Laboratories, Rs.200 a month. (2) Officers of the Bacteriological Department who are Directors of Pasteur Institutes, Rs.100 a month. (3) Deputy Director-General, Indian Medical Service, Rs.400 a month, subject to a maximum of Rs.2500 a month for the total pay and duty allowance combined. (4) Assistant Directors-General, Indian Medical Service (Sanitary) and (Stores), Rs. 250 a month, subject to a maximum of Rs.2500 a month for the total pay and duty allowance combined.

Note.—The appointment of Additional Assistant Director-General, Indian Medical Service, will, for the present, continue to grade for the purposes of pay as a Deputy Assistant Director, Medical Services, Army Headquarters.

2. The rates of overseas pay specified in Para. 1, clause (b), apply only to the officers of the Indian Medical Service in civil employment who fall under Para. 1, clauses (b) to (h). This overseas pay will be drawn by all such officers who were in permanent service on Dec. 1st, 1918, and by all such British officers who have joined or may join the service after that date. Such Indian officers who have joined or may join the permanent service after Dec. 1st, 1918, will not be allowed to draw this overseas pay, unless they are already drawing pay at a higher rate than is admissible without overseas pay, in which case they will continue to enjoy the benefit of that higher rate for so long as they would otherwise have done; but they will not receive any further increment until it is due to them under the scales now sanctioned.

3. Exchange compensation allowance is withdrawn with effect from Jan. 1st, 1920.

4. In bringing officers at present in service on to the revised rates of pay, Articles 156 to 158 of the Civil Service Regulations will not apply. A personal allowance is, however, sanctioned for all existing incumbents of offices, who are drawing a salary greater than that admissible under the scales now sanctioned so as to bring their emoluments up to the amount now enjoyed. These personal allowances will be absorbed as increments are earned.

5. Subject to the provision in para. 4, the initial pay of the scales now sanctioned in the case of an officer who holds an appointment on a time-scale of pay specified in para. 1, clause (a), will be regulated according to the number of years he has held the appointment permanently, and the broken period of a year of service which such an officer has put in before Jan. 1st, 1920, will remain at his credit for the next increment.

Note.—The rates of pay in para. 1, clause (b) apply to all appointments held by officers of the Indian Medical Service in civil employ which are not specified in the remaining clauses of that paragraph. These include, amongst others, the following appointments: Civil Surgeons; Agency Surgeons; Presidency Surgeons, 1st and 2nd Districts, Bombay; Police Surgeon, Calcutta; Senior Surgeon and ex-officio Sanitary Commissioner, Mysore Darbar; Medical Officer, Kathiawar Political Agency; Ophthalmic Surgeon, General Hospital, Rangoon; Medical Officer, Seistan; Director, Medical Department, Bikanir; Medical Officer, Mewar Bhil Corps, Kherwara; Superintendent of Mahableshwar; Superintendent of Matheran; Resident Surgeon, Medical College, Calcutta; Resident Physician, Medical College, Calcutta; Resident Surgeon, Eden Hospital, Calcutta; Resident Medical Officer, General Hospital, Madras; and Assistant Superintendent, Government Maternity Hospital, Madras.

ROYAL NAVAL MEDICAL SERVICE.

Surgeon Rear-Admiral C. S. Woodwright, placed on Retired List at own request.

The following appointments have been made: Surg. Cmdrs. H. Huskinson, W. S. H. Sequeira, S. F. Dudley, and S. Roach, to *President*, additional, for three months' hospital course; and H. W. B. Shewell to *Revenge*, as Squadron Medical Officer; Surg.-Lieut. Cmdr. M. S. Moore to the *President*, additional, for three months' hospital course.

ARMY MEDICAL SERVICE.

Col. S. A. Archer is placed on retired pay on account of ill-health contracted on active service.

ROYAL ARMY MEDICAL CORPS.

Major J. Mackenzie to be temporary Lieutenant-Colonel whilst specially employed.

Capt. R. Ellis retires, receiving a gratuity, and is granted the rank of Major.

Temp. Capt. M. Bates relinquishes the acting rank of Major.

Capt. C. B. Hogg is placed on the half-pay list on account of ill-health.

Temporary Captains relinquishing their commissions and retaining the rank of Captain: W. B. Wilson, B. A. Cheadle, W. L. Young, R. S. Dollard, J. G. M. Sloane, and W. F. Gardener.

Lieut. (temp. Capt.) M. F. D. Graham resigns his commission and is granted the rank of Captain.

SPECIAL RESERVE OF OFFICERS.

The undermentioned Captains relinquish their commissions and retain the rank of Captain: H. Smith and G. Day.

DEFENCE FORCE.

To be temporary Major: J. A. Clark. To be temporary Captains: E. Coplans, T. P. Cole, C. H. Carlton, G. F. Hardy, and A. M. Johnson. To be temporary Lieutenants: O. G. Misquith, C. S Atkin, and P. Lloyd-Williams.

West Riding Field Ambulance (D.F.):—To be temporary Lieutenant-Colonels: J. Mackinnon, F. Whalley, and W. Lister.

TERRITORIAL FORCE.

Lieut.-Col. A. H. Vernon to command the 3rd S. Casualty Clearing Station.

Capt. (Bt. Major) A. Walker to be Major.

Major M. White, R.A.M.C., to be Adjutant of the R.A.M.C. School of Instruction, Welsh Division (T.F.).

Major J. Ward vacates the appointment of D.A.D.M.S. 44th (Home Counties) Division.

Capts. D. S. Sutherland and E. L. Rowse to be Majors.

Capts. A. E. Chisholm (late R.A.M.C.) and J. McKay (late R.A.M.C., S.R.) to be Captains.

Capts. B. G. Goodwin and E. G. Anderson resign their commissions and retain the rank of Captain.

1st London (C. of L.) General Hospital: Major (Bt. Lieut.-Col.) W. McA. Eccles is restored to the establishment.

1st London (C. of L.) Sanitary Company: Capt. H. Holroyd resigns his commission and retains the rank of Captain.

2nd London Sanitary Company: Capt. R. O. Sibley resigns his commission and is granted the rank of Major.

ROYAL AIR FORCE.

R. J. Monahan and J. Craig are granted temporary commissions as Flight Lieutenants.

Obituary.

ALEXANDER WYNTER BLYTH, M.R.C.S. ENG., L.S.A., F.C.S., F.I.C.,

BARRISTER-AT-LAW; PUBLIC ANALYST FOR MARYLEBONE.

THE death on March 30th, in his seventy-seventh year, of Mr. Wynter Blyth has removed a medical man of wide scientific attainment. Born in 1845 at Woolwich, where his father was in practice, Wynter Blyth was educated at King's College, London, of which he later became an associate, qualifying in 1870. He studied law at Lincoln's Inn, being called to the Bar in 1889. Starting in general practice in Devon, he was soon drawn to the preventive side of medicine, first becoming medical officer of health for the North Devon Combined District, and analyst for the county, and then for over 25 years medical officer of health to the Metropolitan Borough of Marylebone, to which body at the time of his death he was still public analyst. Wynter Blyth's literary work met the needs of a large circle of readers. His Dictionary of Hygiene and Public Health, frankly based upon the model set by Tardieu, became a standard work of reference in sanitary science, and helped to bring about much-needed measures of reform. Other large books followed: Foods, their Composition and Analysis; Poisons, their Effects and Detection; Diet in Relation to Health and Work; and a Manual of Public Health. In 1893 he issued his Lectures on Sanitary Law, founded upon a course delivered at the old College of State Medicine, where he was professor of hygiene, and the sound advice to medical officers contained in it enabled many of them to secure more effective hygienic administration in their districts. A friend and colleague writes of him:—

Wynter Blyth was well known among the fellows and members of the Royal Sanitary Institute, to which he had given long and devoted service. He was twice chairman of its Council and for 35 years a member of its board of examiners, on which his cheery manner did much to enliven the arduous duties. About 12 years ago he resigned his position as M.O.H. for Marylebone and confined his energies to analytical work. His ability in this direction soon considerably increased his practice, and he enjoyed in the later years of his life the perfect freedom of thought and action which is not always possible with a municipal officer. Always a hard worker, he recognised the value of recreation, and in recent years he pursued a hobby of farming, on a small scale, at Kintbury, which his technical knowledge helped to make a success. He was a keen automobilist and chess-player. A scientist himself of no mean calibre, he was extremely modest of his own attainments, and remained a student to the end.

With these qualities and attainments Wynter Blyth was called upon to make many public engagements. He presided over the Society of Medical Officers of Health, and he was a Fellow of the Société Française d'Hygiène and of the Italian Society of Hygiene at Milan. His death occurred suddenly while he was at work in his laboratory.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

Public Health (Tuberculosis) Bill.

THE Public Health (Tuberculosis) Bill was considered by Standing Committee B of the House of Commons on April 21st, Sir WATSON RUTHERFORD in the chair.

On Clause 1, which makes further provision with respect to arrangements for treatment, Mr. GRUNDY moved an amendment to secure a review of all existing schemes. His object, he said, was to provide that schemes which might be inadequate might be brought up to the standard of efficiency necessary for dealing with tuberculosis.—Sir A. MOND (Minister of Health) resisted the amendment. It was impossible, he said, to accept in Committee an amendment which changed entirely the character of an agreed Bill, and which, instead of putting matters forward, made what was now much clearer rather more obscure.—Major FARQUHARSON said he could not help feeling admiration for the enthusiasm which certain honourable Members displayed towards what they described as the inadequacy of tuberculous treatment, but when that sentiment was placed *vis-à-vis* to the best scientific opinion, and the results of sanatorium treatment so far, he suggested that they should calm their enthusiasm for extensive and expensive schemes of treatment until the experimental stage of these treatment methods had been passed. Scientific opinion at the present time had great doubts as to the effect of sanatorium treatment in doing anything more than palliating for a short time the unfortunate position of the tuberculous person. Only the other day a magnificent book was published written by one of America's greatest physicians, who had made tuberculosis a special study. The sum and substance of the conclusions of this very distinguished American scientist was that a tuberculous free population in this country would be absolutely unequipped for existence. In other words, if they took a group of 20 or 25 children and reared them until they were of adult age under conditions which precluded the possibility of tuberculous infection, and the time came when they would have to go out into the world free of the restrictions which had kept them tuberculous free, they would inevitably succumb, one after the other, to the infection, which would be so extreme that it would sweep them away in a state of tuberculosis in no time. Therefore he asked the Committee not to seek to impose standards of adequacy upon local authorities, but to accept the position as it was now. The more he read up-to-date science, and the older he became, the more he was thrown back on the wisdom of our grandmothers and grandfathers. The average grandmother knew that a child was to have measles, scarlet fever, and all the rest of the zymotic diseases, and very properly and very scientifically she exposed her children to those diseases, because the occurrence of that disease gave them immunity. Precisely the same thing happened in regard to tuberculosis. It was part of Nature's freely given immunity to the population of this country that the small doses of tuberculous infection that we did get acted as a protection against a more severe attack, and gave us in a measure the physical equipment to stand what Mr. Mantalini described as the "demnition climate" of this country. We could not expect, and in fact it would not be wise economically, scientifically, or in any other way, for our people to seek to become tuberculous free. The Committee would do well not to alter the Bill, which was a really good equipment for the purpose in view.—Captain ELLIOT said he would vote in favour of the Bill as it stood, because, although he did not agree with some of the speeches that had been made, he thought the essential thing was to get the coöperation of the local authorities. It would cause the greatest injury to public health if it came to be supposed that a policy was being dictatorially settled at Whitehall and forced upon a reluctant set of local authorities.—On a division the amendment was rejected by 23 votes to 10.

Sir R. THOMAS moved an amendment, the purpose of which was to acknowledge in the Bill the King Edward VII. Welsh National Memorial Association, which is the approved authority in Wales at the present time.—Sir A. MOND accepted the amendment which was agreed to.

Sir H. NIELD moved an amendment under which a council shall not be deemed in default as a result of the withdrawal of or diminution in the rate of the Exchequer contributions. It would be a monstrous thing to have the whole expense transferred to the councils. It had been known in other Departments—he excluded any reference to the present Ministry of Health—that work had been done on the basis of a contribution from the Exchequer, and as time went on they had managed very skilfully to withdraw their own contribution, and to leave the unfortunate ratepayer to bear the whole burden of the work which the Government had induced.—Sir A. MOND said that although he felt that this amendment was of an ultra precautionary nature, in order to allay any anxiety he would accept it.—The amendment was agreed to.

On Clause 3, which gives power to councils to act through committees, Mr. T. THOMSON moved an amendment to make obligatory the coöption of persons specially qualified. He hoped that the Minister would see his way to redeem the pledge given by his predecessor that the members of Insurance Committees should be specially nominated and coöpted on to the local authority.—Major FARQUHARSON said he had every respect for the members of these committees, but after all they had merely a pen-and-ink experience of the administration of tuberculosis. Instead of the legislature seeking to strike at the autonomy of the local authorities it ought really to strengthen them. The local authority that had a certain measure of confidence reposed in it to use its own discretion in these matters was one from which they would get far more effective work than if they imposed all sorts of trumpery conditions.—The amendment was negatived.

Mr. TYSON WILSON moved a new clause providing for after-care of tuberculous patients by councils.—Sir A. MOND said that although he could not bind himself to accept the exact wording of the clause he would agree to the principle.—The new clause was agreed to.

Dr. NATHAN RAW moved a new clause providing that the Seamen's National Insurance Society should be deemed to have the same status, powers, and duties as any council of any county or county borough. He said seamen arriving at any port in this country were no longer able to receive sanatorium benefits under the Insurance Act. He wished to ask the Minister if he would consider the question of setting up some central committee which would be able to deal with all seamen at any port of entry in this country and allow them to receive sanatorium benefit.—Sir KINGSLEY WOOD said this society had done very excellent work on behalf of the seamen. But only half of the seamen of the country belonged to the society, and, of course, the other half under the Insurance Act got their benefits one way or another through the Insurance Committees. The Minister recognised the considerable difficulty these men had in obtaining benefit, and he would confer with Dr. Raw and others interested to see if anything could be done. The Minister would do all he could in connexion with this excellent society.—The CHAIRMAN said the clause was out of order and he could not put it to the Committee. He had allowed a few remarks upon it in order to elicit some statement from the Government on the matter.

The Committee stage of the Bill was completed and the measure as amended was ordered to be reported to the House.

HOUSE OF COMMONS.

WEDNESDAY, APRIL 20TH.

Bonus to Tuberculous Ex-Service Men.

Mr. MYERS asked the Minister of Pensions whether local war pensions committees had, for many months past, been asking for a ruling with regard to the payment of bonus to ex-Service men suffering from tuberculosis admitted as attributable to or aggravated by service who had completed a course of training arranged by local insurance committees; and whether he would state the reason why these men were deprived of benefits enjoyed by all other ex-Service trainees.—Mr. ALFRED DAVIES asked the Minister of Health whether he was aware that ex-Service men suffering from tuberculosis accepted as attributable to or aggravated by service, who underwent a recognised course of training arranged by the local insurance committees, were unable to obtain payment of the bonus paid on termination of courses of training arranged by the Ministry of Labour, or, in the case of concurrent training and treatment, by the Ministry of Pensions; whether he could explain why these men should be thus penalised; and whether he would take steps to ensure that these trainees should enjoy the same benefits as other disabled ex-Service men.—Mr. IAN MACPHERSON (Minister of Pensions) replied: The training bonus is payable in cases where a disabled man, who is obliged in consequence of his disability to change his pre-war occupation, has satisfactorily completed a course of training which is certified by representatives of the trade as adequate to equip him for his new occupation. It is the practice of my Department and of the Ministry of Labour to secure trade approval both of the course of training and of the individual trainee in order to provide the man with the best chance of securing regular and permanent employment in the new trade he has selected. So far as men suffering from tuberculosis have received training of this character in any class of institution the bonus has been paid. Difficulty has, I understand, been experienced by the Ministry of Health with regard to the provision of courses of instructions in technical trades, and in such trades the training at present given is, for the most part, of an elementary kind and cannot be regarded as regular vocational training. I am, however, in communication with the Ministry of Health on the matter.

Anatomical Study in Great Britain.

Sir HARRY BRITTAIN asked the Minister of Health whether he was aware that there was the greatest difficulty with regard to the proper prosecution of anatomical study in this country, and that, in consequence, a large number of British medical students were forced to prosecute or complete their studies in foreign hospitals or universities; whether this difficulty was mainly due to the inadequate supply of dead bodies for anatomical purposes; and whether he would consider appointing a Select Committee to inquire into the matter.—Sir A. MOND replied: Although it is the case that owing to the difficulty in obtaining subjects British students have occasionally gone abroad to seek facilities for the study of anatomy in foreign schools; this state of affairs has now been remedied by the action taken by my predecessor. There is still a shortage in the case of certain provincial medical schools, but this is being remedied.

Shell-shock and Tropical Climates.

Sir WALTER DE FRECE asked the Minister of Pensions whether he was aware that many ex-officers and men who went out to the tropical parts of the British Empire to seek their livelihood were being sent home or were returning home suffering from the effects of shell-shock which apparently manifested itself seriously in hot climates; whether many of these men were now seriously embarrassed financially; and whether he would give instructions that all such cases were to be dealt with as expeditiously and sympathetically as possible.—Mr. MACPHERSON replied: I am not aware of the circumstances referred to in the first part of the question, but special consideration is given to all cases in which there is urgency in order that there may be no delay in providing whatever benefits are admissible under the Royal Warrant. If my honourable friend has any particular case in mind I shall be glad to investigate it.

Medical Examinations for the Navy.

Sir THOMAS BRAMSDON asked the Secretary to the Admiralty whether, in view of the stringent medical examination applied to new entries in peace time, which should make attributability more pronounced in the case of death or invaliding, some form of independent appeal board would be instituted to deal with any post-war cases in dispute, observing, for instance, that pneumonia might be clearly due to the service on which the man was employed, but that there was no machinery for recording or giving due consideration to the circumstances attending each case, nor for bringing them to the notice of the medical officers concerned whose duty it was to decide this important matter at present.—Mr. AMERY (Parliamentary Secretary to the Admiralty) replied: As my predecessor informed the honourable Member in reply to his question of March 21st, it is not considered that any form of independent appeal board is necessary. I cannot agree with the statements in the latter part of the honourable Member's question. From the time a man enters the Royal Navy to the time he leaves it a careful record is kept of his medical history, and before any man is invalided for injury or disease all the details of such injury or disease are fully known to the board of survey, who definitely give their opinion as to attributability on special forms provided for the purpose. Such a disease as pneumonia might well in exceptional cases be definitely given as attributable to service. The surveying officers are medical men intimately acquainted by personal experience with the conditions of life at sea, and the Admiralty consider that no more efficient machinery could be devised for deciding the question of attributability. The same considerations apply to the death of a man or officer.

Rules under Nurses Registration Acts.

Mr. FREDERICK HALL asked the Minister of Health whether he was aware that, though Acts to provide for the registration of nurses received the Royal Assent on Dec. 23rd, 1919, the English Act had, so far, not been carried into effect, and that efforts were being made departmentally to coerce the General Nursing Council of England and Wales to agree to provisions incorporated in the rules framed under the Scottish Act, of which that council did not approve; whether such provisions, if adopted, would have the effect of reducing its authority in certain important directions to that of a recording body under the Scottish Board of Health, without power of discrimination; and whether he would inquire into this matter with a view to satisfactory regulations being brought into force without further delay.—Sir A. MOND replied: The honourable Member is under a misapprehension. The General Nursing Council submitted a rule purporting to give them a discretion to refuse to admit to their register nurses already on the Scottish and Irish registers. I am advised on the highest authority that this is ultra vires, and I am bound to ask the Council to amend the rule in question so as to bring it into conformity with the Act. Subject to the submission of an amended rule to give effect to the reciprocity provisions of Sections 6 (3) of the Act, I am prepared to sanction at once the rules for the admission of existing nurses. I cannot accept the suggestion contained in the latter part of the question, but in any case I have no power to sanction a rule in the form desired by the Council.

Mr. Hollomby's Pension Appeal.

Mr. RONALD MCNEILL asked the Attorney-General if he would explain the reason for the decision of the appeal tribunal of the Ministry of Pensions in the case of Mr. E. G. Hollomby in which it was decided that two medical boards were wrong in stating that the disability of the pensioner was due to his military service; and what medical authority was responsible for the advice on which the decision was based.—Sir G. HEWART replied: I am informed that the decision of the Pensions Appeal Tribunal deputed to hear and decide this appeal was based upon the whole of the evidence put forward, both oral and documentary. Each tribunal is composed of three members, a legal member as chairman, a doctor as medical member, and an ex-Service man or non-commissioned officer as Service member. The decision of a tribunal is by a majority of votes. In the case under notice the decision was unanimous.

THURSDAY, APRIL 21ST.

New Government Light Metal Limb.

Major COHEN asked the Minister of Pensions if he would state the price of the new Government light metal limb, both as supplied by Messrs. Vickers and also when completely fitted with bucket, &c.—Mr. IAN MACPHERSON replied: It would not be expedient at this stage to publish details of the contracts placed with the limbmakers in connexion with the new light metal limb. I may, however, inform my honourable and gallant friend that for the first issue of 500 the total cost per limb will not exceed £30. These limbs are, of course, provided free to the pensioner.

House of Lords Pension Appeals.

Mr. ALFRED T. DAVIES asked the Minister of Pensions whether he was aware that there were some thousands of cases of ex-Service men waiting to be heard before the House of Lords Appeal Court, of which only about 40 cases per week were now being dealt with; and whether, if it was not possible under existing regulations to set up additional courts of three justices of the peace in various centres to deal with the urgent need for speedy decisions in these cases, he would consider an amendment of the existing law so as to deal with this urgent matter in the interests of ex-Service men during the present session.—Sir G. HEWART (Attorney-General) replied: I have been asked to reply. I am informed that there are at the present time about 8,500 appeals waiting to be dealt with by the Pensions Appeal Tribunals established by the War Pensions (Administrative Provisions) Act, 1919. The 12 tribunals now sitting deal with over 600 appeals per week. Of the cases listed, some have to be adjourned often owing to the failure of appellants to appear in response to the notices of hearing. Steps are being taken to ensure as far as possible that there shall be no unreasonable delay, and to this end additional tribunals are being set up.

Sir THOMAS BRAMSDON asked the Minister of Pensions what would be the total pension on demobilisation at the end of four and a half years' war service of an able seaman, called up, who had previously been invalided with tuberculosis after ten years' service; how much of this pension would be in respect of his war service; and what pension an able seaman with only one year's service, and invalided during the war with tuberculosis, would receive on discharge; and would he take steps to rectify any inequality that might exist in dealing with these cases.—Mr. MACPHERSON replied: The general position regarding men invalided and pensioned before the war who were called up for service was indicated in the reply given to the honourable Member on March 17th. The pension of a seaman, reassessed on demobilisation, would not ordinarily be increased in respect of a total of less than 15 years' service, unless during his mobilised service he had been advanced to leading rate or had earned additional good conduct badge. As regards the seaman invalided during the war, if the disability was attributable to or aggravated by service, he would receive a pension in accordance with the degree of disablement so long as the disablement or aggravation persisted, but when this was no longer the case, compensation would cease. The pensioner called up has, however, in any case a permanent pension. I may add that the question of specially increasing pre-war life disability pensions in the cases of men who served again in the Great War is under consideration, and it is hoped that it may be possible to make an announcement at an early date.

Supply of Meals to Children in Mining Areas.

Mr. FORREST asked the President of the Board of Education how many educational authorities were now supplying meals to the children in the mining areas; and what was the aggregate number of children thus aided.—Mr. FISHER replied: The returns which I have received from local education authorities as to the action taken by them under the Education (Provision of Meals) Acts do not enable me to distinguish between those portions of the authorities' areas which are mining districts and the remaining portions. However, during the week ended April 9th, 1921, the latest week for which complete returns have been received, meals were being provided by 35 local education authorities in whose areas mining is one of the predominant industries; the number of children fed was, approximately, 12,000. From the returns for the week ended April 16th, which are not yet complete, it is clear that there was a substantial increase in the number of children being fed.

Medical Equipment in Irish Auxiliary Force.

Mr. HENRY (Attorney-General for Ireland), replying to Captain REDMOND, said that he was satisfied that the arrangements at present in operation were sufficient to ensure the maintenance of the highest standard of discipline in the Auxiliary Forces in Ireland.—Lieutenant-Colonel GUINNESS: Apart from the question of discipline, would it not be an advantage to this gallant force to be directly under the Commander-in-Chief, as at present no one seems to be in a position adequately to arrange for their medical necessities or administrative needs?—Mr. HENRY: There are many difficulties in the way of bringing a force of this kind under military control. In the martial law areas they are under military control.—Lieutenant-Colonel GUINNESS: Is the right honourable and learned gentlemen aware that they have no medical staff of any kind, and that when men get wounded they have to undergo great and unnecessary suffering in consequence?—Mr. HENRY: The military medical system is at their disposal and I have promised to have the matter dealt with.—Captain ELLIOT: Will the right honourable gentleman remember that during the war every force, however small, had to have a medical equipment, even small infantry units; and can he say how it is that these units under active service conditions take the field without any medical equipment whatever?—No answer was given.—Sir J. D. REES: Will the right honourable gentleman arrange to use some of the redundant doctors in the Health Department for this service?—No answer was given.

Local Authorities (Disqualification Removal) Bill.

Mr. ORMSBY-GORE presented the Local Authorities (Disqualification Removal) Bill, a measure to relieve members of local authorities from disqualification for office by reason of the receipt of medical or surgical relief in cases of sudden or urgent necessity. The Bill was read a first time.

MONDAY, APRIL 25TH.

Public Health (Tuberculosis) Bill.

The Public Health (Tuberculosis) Bill, as amended in the Standing Committee, was considered on report, when Major HENDERSON moved a new clause in similar terms to that moved by Dr. Nathan Raw in Committee, delegating certain powers to the Seamen's National Insurance Society. He moved it to find out whether the Government were prepared to meet him in any way.—Captain ELLIOT seconded the clause. He agreed that perhaps as it stood the clause would not commend itself either to the House or to the Minister in charge of the Bill.

They were intending, in conference with the officials of the Ministry, to work out a new clause which might be more suitable, and they had arrived at one which they thought had met the opinion of the Minister. But there had not been time to get the new clause on the order paper for that debate. He hoped that the Minister would give a pledge that in the House of Lords he would, if possible, incorporate a clause of this character in the Bill.—Sir A. MOND, Minister of Health, said he was quite ready to undertake that the agreed clause should be inserted when the Bill reached the House of Lords in order to meet a very long-felt want.—Major HENDERSON said that in view of what Sir A. Mond had said he would withdraw the clause.—The report stage was concluded, and the Bill was read a third time.

TUESDAY, APRIL 26TH.

Training of Men Disabled in Former Wars.

Mr. WILLIAM GRAHAM asked the Minister of Labour whether his attention had been called to the fact that men disabled in former wars, and particularly in the Boer War, had within recent years found it impossible to continue in their usual callings on account of ill-health or partial breakdown arising from their disablement; and whether, in view of the fact that the number of such men was comparatively small and that they had suffered great hardship, he would take steps to secure for such cases as were suitable the training for another trade or occupation which was accorded to men disabled in the late war and under conditions similar to those which governed that training.—Sir MONTAGU BARLOW (Parliamentary Secretary to the Ministry of Labour) replied: I am informed that one or two applications of this sort have been received. We have no power to provide training for such men and in view of the difficulty of providing training for the substantial number of men disabled in the late war who yet remain to be trained, I regret I do not see my way to accepting my honourable friend's suggestion.

Killarney Motor Ambulance Commandeered.

Mr. ACLAND asked the Secretary for War whether the troops at Killarney still needed a motor ambulance; and, if so, whether one would be provided by the War Office, so that the ambulance commandeered some months ago from the local health authority might be restored, as its absence was causing suffering to sick and infirm people.—Sir L. WORTHINGTON-EVANS replied: I am informed that the military authorities took possession of the ambulance in question, as it had not been used for any lawful purpose for a long time and no permit for it had been applied for. It was last used for the unlawful conveyance of rebels to Killorglin Fair, where it was damaged. It is not proposed to hand it back to the local authorities.

British Seafarers and Venereal Disease.

Mr. SIMM asked the Minister of Health if he was aware that British seafarers still suffered under disabilities unshared by their fellow-countrymen or by foreign seamen in being penalised if they sought treatment for venereal disease, and that the British representatives at the meeting of the health section of the League of Nations were advocating international facilities for the free treatment of seafarers; and, if the Government would consider the desirability of amending the Merchant Shipping Act, 1906, Section 34, Subsection (1), as desired by all interests concerned.—Sir ALFRED MOND replied: I apprehend that the honourable Member is referring to the treatment of British seamen in foreign ports. I am aware that the same facilities as are provided in British ports for the treatment of seamen suffering from venereal disease are not available in many foreign ports. This matter is under consideration by the Committee of the Office International d'Hygiène Publique, and will in all probability be dealt with by the International Health Organisation which is now being established under the League of Nations. I will consult with my right honourable friend the President of the Board of Trade in regard to the last part of the question.

PEOPLE'S LEAGUE OF HEALTH.—Sir George Newman received a deputation on April 20th of representatives of the medical members of the People's League of Health. The deputation was introduced by Sir Bruce Bruce-Porter, and included Lieut.-Colonel F. E. Fremantle, M.P., Sir G. Sims Woodhead, Dr. A. Latham, Sir Harry Baldwin, and Professor Edgar Collis. Miss Olga Nethersole, hon. organiser, was also present. The deputation discussed with Sir George Newman the past and future work of the People's League of Health. Sir George Newman concurred in the views of the deputation as to the great importance of public education in hygiene, and said that he would be glad to coöperate at any time with the medical representatives of the League in providing them with information as to the work of the Ministry.

Medical News.

UNIVERSITY OF MANCHESTER.—The following appointments have been made by the Council: Mr. A. G. Lobley, Reader in Electro-Chemistry; Mr. E. D. Telford, Lecturer in Practical Surgery; Dr. John Sutcliffe, Clinical Lecturer in Mental Diseases; Dr. David Orr, Lecturer in Mental Diseases.

UNIVERSITY OF GLASGOW.—The following degrees were conferred on April 26th:—

Doctor of Medicine.—John C. Young.

Bachelors of Medicine and Bachelors of Surgery.—Annie M. Alexander, Marjorie M. Anderson, Adam Barr, Rosa Bass, Elizabeth M. V. H. B. Bird, Elizabeth E. Brown, Murdoch Brown, Ellen B. Cowan, Douglas R. F. Davidson, Peter A. Faichney, Elizabeth J. Findlay, Colin M. Forbes, Agnes M. Gibson, Francis D. Gillespie, Mary A. Grant, Brunnhilde M. Grieve, William M. Sinclair, Louis Sivo, Elizabeth H. M. Slimmon, Christina S. Stoddart, William R. P. Templeton, George Tudhope, Richard J. Watson, Lilian J. Taylor White, Robert H. Williamson, George S. Wilson, Peter A. Wilson, and Elizabeth Young.

UNIVERSITY OF LONDON.—A course of eight advanced lectures in Physiology will be given in the Physiological Laboratory, St. Bartholomew's Hospital, at 4.30 P.M., on Tuesdays, beginning on May 3rd, when Professor W. D. Halliburton, F.R.S., will lecture on Cerebrospinal Fluid. Subsequent lectures will be delivered by Professor M. S. Pembrey on the Secretion of Milk (May 10th); Dr. J. Barcroft, F.R.S., on Alpinism (May 17th); Professor W. M. Bayliss, F.R.S., on the Reaction of the Blood (May 24th); Professor J. B. Leathes, F.R.S., on Tyrosine (May 31st); Professor E. H. Starling, F.R.S., on the Heart in Exercise (June 7th); Dr. H. H. Dale, F.R.S., on Anaphylaxis (June 14th); Dr. Leonard Hill, F.R.S., on the Capillary Circulation (June 21st).—A course of eight lectures on Reception of Sensory Stimuli will be given by Professor H. E. Roaf in the Physiology Theatre, London Hospital Medical College, at 4.30 P.M. on Thursdays, beginning on May 12th. Attendance at these courses is recognised in connexion with the B.Sc. (Honours) Degree in Physiology. The lectures are addressed to advanced students of the University and to others interested in the subject. Admission is free, without ticket.

ROYAL COLLEGE OF SURGEONS IN IRELAND.—At a meeting of the President, Vice-President, and Council it was unanimously resolved to confer the Honorary Fellowship of the College upon the following American surgeons: W. J. Mayo and C. H. Mayo, Mayo Clinic, Rochester, U.S.A.; Geo. E. Brewer, New York; Geo. W. Crile, Cleveland, Ohio; Richard H. Harte, Philadelphia; W. W. Keen, Philadelphia; John M. T. Finney, Baltimore; A. J. Ochsner, Chicago. It is hoped that the ceremony will take place in the early autumn.

ULSTER EYE, EAR, AND THROAT HOSPITAL, BELFAST.—The annual meeting of this institution was held on April 22nd, Alderman Davison, High Sheriff of Belfast, presiding. The annual report showed that the patients were drawn from all the Ulster counties, the in-patients numbering 531. The total number of operations was 642. The attendances of new and old patients numbered 6966. Various improvements in the internal arrangements of the hospital have been effected and others are in contemplation. The financial statement is highly satisfactory. There has been a substantial increase in subscriptions and the hospital has paid its way. Regret is expressed at the death of Mr. John Atkinson, who as hon. treasurer gave many years of devoted service to the institution. A part-time paid secretary has been appointed. Dr. W. M. Killen, the senior surgeon to the hospital, mentioned that the negotiations between the hospital and the Belfast Ophthalmic Hospital for the amalgamation of the two hospitals has not yet borne fruit, but he hoped that such an amalgamation would come in the future. A cordial vote of thanks to the chairman was passed on the motion of the Dean of the

The date of the postponed Census has now been fixed for Sunday, June 19th.

Sir Arthur Newsholme arrived on April 25th at Liverpool on board the s.s. *Carmania* after completion of his engagement at Johns Hopkins University.

Great Northern Central Hospital. — The second half-yearly house-to-house collection organised by the hospital commences on Monday next, May 2nd, and continues during the week.

National Hospital for the Paralysed and Epileptic.—The board of management has decided to appoint a separate officer in charge of the electro-therapeutic department. The work has hitherto been carried out by the registrar.

Hospital for Sick Children, Great Ormond-street.—The annual meeting of the Court of Governors will be held on Tuesday, May 3rd, at 4 p.m., the Prince of Wales, President of the Hospital, in the chair.

The next course of lectures by the Gresham Professor of Physic will be delivered by Sir Robert Armstrong-Jones on May 2nd, 3rd, 4th, and 6th at 6 o'clock each day. The subject will be Our Drinks—Water, Milk, Wines, Ales, and Spirits. The lectures are free to the public and are held at Gresham College, Basinghall-street, E.C.

Royal Institution of Great Britain.—On Tuesday, May 3rd, at 3 p.m., Professor Arthur Keith, will give his third lecture on Darwin's Theory of Man's Origin (in the Light of Present Day Evidence). On Thursday, May 5th, at 3 o'clock, Dr. C. S. Myers delivers the first of two lectures at the Royal Institution on Psychological Studies: (1) The Localisation of Sound, and (2) the Appreciation of Music. On Saturday, May 7th, Professor E. C. C. Baly begins a course of two lectures on Chemical Reaction. The Friday evening discourse on May 6th will be delivered by Sir Robert Robertson on War Developments of Explosives, and on May 13th by Dr. W. Bateson on the Determination of Sex.

Donations and Bequests.—The Vice-Chancellor of the Lancashire Chancery Court has approved of a scheme for the application of the interest for charitable purposes of a sum of £40,000 left by the late Mr. J. T. Blair, a Manchester merchant, who died in 1917. The testator directed that the income of the fund be devoted to the assistance of hospitals, infirmaries, rest-houses, and for individual necessitous poor, especially distressed gentlefolks who had fallen on evil times, and other benevolent objects, including the Manchester and Salford Street Children's Mission.

New Principal of Livingstone College.—Dr. Loftus E. Wigram has resigned his post as principal of the College on grounds of health. During the war he carried on a military auxiliary hospital in the College buildings, for which he was twice mentioned in despatches. The committee have appointed as his successor Dr. Tom Jays, who has served since October, 1919, as Vice-Principal. Dr. Jays, formerly a missionary of the Church Missionary Society, has had good experience in many tropical countries, especially in West Africa. As travelling secretary of the Student Volunteer Missionary Union he has visited the chief universities and colleges of Great Britain and of the United States. By his appointment the continuity of the work of the College will be maintained. It is hoped still to retain the services of Dr. Wigram as a lecturer.

Royal West Sussex Hospital.—The annual report of this hospital states that the income during 1920 showed an increase over that of 1919 of £1859 17*s.* 7*d.*; the expenditure exceeded the income by £949 9*s.* 7*d.*, and this has prompted the governors to appoint a special subcommittee to consider the whole question of paying patients. The governors have already been suggesting to in-patients this means of raising income, and the result has been very satisfactory, so far £1156 having been raised in this way. A promising start has also been made with a scheme by which all employed men and women in the district served by the hospital are subscribing a small sum weekly. In 1920 the in-patients reached the record number of 1008, against 858 in 1919, while there were 1111 out-patients; 495 patients receiving X ray treatment and 868 operations under anæsthesia were performed. The year also marked the completion of the various improvements undertaken with the gift of £2000 from the British Red Cross Society. At the annual meeting of the governors on April 19th general approval was expressed towards the paying patients' scheme; and the necessary authority was given the vernors to sell out investments, or transfer from the iness account, a sum sufficient to pay off the deficit of

Memorial to the late Dr. T. A. Johnston.—A memorial tablet to the late Dr. Thomas Arnold Johnston, assistant physician and pathologist to the Leicester Royal Infirmary, commemorating his work at the infirmary, was unveiled on April 20th by Dr. N. C. Ridley.

Condemned Foodstuffs.—The Manchester Port Sanitary Authority during the past month condemned 394 tons of foodstuffs, including 225 tons of rabbits, on the ground that they were unfit for human consumption.

Provision of Meals Act.—The Lancashire Education Committee has decided to put the Provision of Meals Act into force in 15 townships, which embrace a large mining community.

Rontgen Society.—A provincial meeting of this Society will be held in Manchester on May 6th and 7th. On May 6th, at 4.30 p.m., short papers and demonstrations will be given by J. R. Clarke, M.Sc., on the Measurement of High Voltages; by Mr. E. C. McKinnon, on Storage Batteries in Science and Commerce, with exhibits of typical units for high and low voltage batteries; by Professor A. V. Hill, F.R.S., on the Psycho-Galvanic Reflex, the Hot Wire Sphygmograph; by Professor W. L. Bragg, F.R.S., on Models of Crystal Structure, X Ray Bulbs designed to give Monochromatic Radiation, the X Ray Spectrometer; and by Dr. A. E. Barclay, on Viewing-box for 300 Reductions, Potter-Bucky Diagram, Pirie Photometer. At 7.30 p.m. Professor Bragg will speak on the Structure of Metals as Analysed by X Rays, and the Director of Radiological Research, Royal Arsenal, Woolwich, on Radiological Research as applied to the Examination of Metals. On Saturday, May 7th, visits will be paid to the following works: (1) Metropolitan Electrical Co., Ltd. (Westinghouse); (2) Chloride Electrical Works (Storage Batteries); (3) Glover's Cable Works, Trafford Park; (4) Hans Reynolds Chain Works; (5) Ford's Motor Works, Trafford Park; (6) Radium Institute, Manchester; (7) X Ray and Electrical Departments, Royal Infirmary, Manchester. Further particulars can be had from Dr. R. W. A. Salmond, 51, Welbeck-street, London, W. 1.

Dinner to Mr. R. A. Bickersteth, of Liverpool. On the occasion of his resignation from the position of senior surgeon to the Liverpool Royal Infirmary Mr. Bickersteth was entertained to dinner in the Adelphi Hotel by more than 60 of his colleagues and friends on April 20th. The chair was taken by Mr. H. Wade Deacon, who was supported by the Vice-Chancellor of the University (Professor J. G. Adami), the pro-Chancellor (Mr. Rathbone), Dr. Richard Caton, Mr. F. T. Paul, Mr. Holford Harrison, and Mr. Harold Bickersteth. Apologies for absence were sent by the President of the Royal Society (Professor C. S. Sherrington), Sir Robert Jones, Professor G. R. Murray (Manchester), Professor H. Briggs, and others. After dinner the toast of "The Guest" was submitted by Dr. Caton. He paid a warm tribute to the many distinctions won by members of the Bickersteth family in surgery, in the church, and in law, and proceeded to speak in terms of high praise of the guest as a man of culture, a loyal and warm friend, and a distinguished surgeon. The toast was supported by Mr. F. T. Paul and Mr. Frank Jeans as old colleagues of Mr. Bickersteth, and by Mr. K. W. Monsarrat, Mr. G. P. Newbolt, and Mr. D. Douglas-Crawford, as representatives of the other Liverpool hospitals, and was drunk with musical honours. Mr. Bickersteth replied in feeling terms.

It is a matter of historic interest that three generations of the Bickersteth family have been on the staff of the Royal Infirmary, and the resignation of Mr. Bickersteth breaks a link that has lasted for more than a hundred years.

SOCIETIES.

ROYAL SOCIETY, Burlington House, London, W.
Thursday, May 5th.—4.30 P.M., Croonian Lecture:—Dr. H. Head: The Release of Function in the Nervous System.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Monday, May 2nd.

SECTION OF TROPICAL DISEASES AND PARASITOLOGY: at 8.30 P.M.
Papers: Dr. A. F. MacCallan: The Ankylostomiasis Campaign in Egypt, 1913-1915.
Sir Leonard Rogers: The Mortality and Prognosis of Cholera treated by the Author's Hypertonic Saline Method, based on 2000 Cases.

Tuesday, May 3rd.

SECTION OF SURGERY: SUBSECTION OF ORTHOPÆDICS: at 5.30 P.M. (Cases at 5 P.M.)
Cases: Cases of Special Interest or demonstrating Special Methods of Bone Grafting will be shown by Mr. E. W. Hey Groves, Mr. O. L. Addison, and others.
Ordinary cases of successful bone grafting will not be shown.

Thursday, May 5th.

SECTION OF OBSTETRICS AND GYNÆCOLOGY: at 8 P.M.
Annual General Meeting—Election of Officers and Council for 1921-1922. (Names already circulated.)
Short Communication: Mr. Henry Curtis: Angioma of the Vagina Spontaneously Evacuated.
Specimen: Dr. Russell Andrews: Carcinoma originating in an Adenomyoma of the Uterus.
Discussion: On "The Causes and Treatment of Sterility," to be opened by Dr. A. E. Giles.

Friday, May 6th.

SECTION OF LARYNGOLOGY: at 4.45 P.M. (Cases at 4 P.M.)
Annual General Meeting—Election of Officers and Council for 1921-1922. (Names already circulated.)
Cases will be shown by—
Mr. Layton, Dr. A. J. Hutchison, Dr. Kelson, and others.

SOCIETY OF MEDICAL OFFICERS OF HEALTH (NAVAL, MILITARY, AND AIR FORCE HYGIENE GROUP), at the Royal Army Medical College, Grosvenor-road, S.W.
Friday, May 6th.—4 P.M., Demonstration:—Lieut.-Col. P. S. Lelean: Sanitary Appliances of Interest to all Health Officers.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W.C.

Births, Marriages, and Deaths.

BIRTHS.

KELLY.—On April 25th, at Malta, to Honor, wife of Major W. D. C. Kelly, R.A.M.C., D.S.O.—a son.

MARSHALL.—On April 18th, at St. Mary Abbotts-terrace, Kensington, the wife of Geoffrey Marshall, M.D., M.R.C.P., of a son.

MARSHALL.—On April 19th, at Dartmouth-place, Blackheath Hill, the wife of R. P. Marshall, M.R.C.S., L.R.C.P., of a daughter.

WHARRY.—On April 17th, at Chester-terrace, Regent's Park, London, the wife of H. M. Wharry, M.R.C.S., of a daughter.

MARRIAGES.

ATKINSON—HAMERTON.—On April 20th, at Hampstead, Arthur E. Atkinson (Major, late R.A.M.C.), to Mrs. G. A. Hamerton, of Belsize-park-gardens, N.W.

COX—HARRIS.—On April 25th, at Cholmeley Hall, Highgate, Hedley Chave Cox, M.B., B.S., M.R.C.S., to Frances Maude Mary, younger daughter of Mr. and Mrs. Harris, of Whetstone.

FISHER—HAYTHORNTHWAITE.—On April 20th, at All Saints Church, King's Langley, Reginald Fisher, M.B., B.C., to Grace, younger daughter of the Rev. and Mrs. T. P. Haythornthwaite, of King's Langley.

WEBER—UNGER-LAISSLE.—On March 17th, Dr. Frederick Parkes Weber to Hedwig Unger-Laissle, M.D.

DEATHS.

BURTON-BROWN.—On April 21st, at 114, Tonbridge-road, Maidstone, Gerald Burton Burton-Brown, M.D., retired, R.N., youngest son of the late T. E. Burton-Brown, M.D., C.I.E.

COOKSON.—On April 22nd, at Pendower, Cheltenham, Surgeon-Major Henry Cookson, F.R.C.S., late Indian Medical Service, aged 88.

GREAVES.—On April 24th, at Friar-gate, Derby, Charles Augustus Greaves, M.B., LL.B., aged 79.

HAWKINS.—On April 21st, at the Military Hospital, Belfast, Captain Wilfred F. Hawkins, R.A.M.C., aged 29 years.

JULER.—On April 23rd, at Alexandra Court, Queen's Gate, Henry Edward Juler, F.R.C.S.

LAURIE.—On April 22nd, at the Red Bungalow, Wadebridge, Cornwall, Cæsar Robert Laurie, Lieutenant-Colonel, R.A.M.C. (T.F.), M.R.C.S., L.R.C.P., L.S.A., aged 64.

MANN.—On April 25th, at Elendery, Rhos-on-Sea, William Slingsby [illegible]nn, M.R.C.S., formerly of Edgbaston, in his 85th year.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages and Deaths.

BOOKS, ETC., RECEIVED.

Notes, Short Comments, and Answers to Correspondents.

QUALITY OF PROTEIN IN NUTRITION.[1]

BY R. H. A. PLIMMER, D.Sc.

OF the three main groups of compounds composing our normal diet, protein is the only one which shows any marked variation. *The carbohydrates and fats are converted* during digestion into a few simple compounds, such as grape sugar, glycerine, and fatty acids. Protein is also converted during digestion into simple compounds, but their number and variety is large, and different amounts of them arise from *the different* proteins. We can thus speak of quality of protein, but not of quality of carbohydrate and fat.

Our usual classification of proteins already indicates their differences, but the variety is *really far greater*. We need only refer to their chemical analysis. Fischer and Kossel and their pupils have shown that proteins on hydrolysis break down into some 18 or 20 amino-acids. These numerous products can be arranged for convenience into eight groups:—

1. *Simple Mono-amino-acids.*

Glycine,
$CH_2(NH_2).COOH.$
Alanine,
$CH_3.CH(NH_2).COOH.$
Valine,
$(CH_3)_2:CH.CH(NH_2).COOH.$
Leucine,
$(CH_3)_2:CH.CH_2.CH(NH_2).COOH.$
Isoleucine,
$(CH_3)(C_2H_5):CH.CH(NH_2).COOH.$

2. *Mono-amino Dibasic Acids.*

Aspartic acid,
$HOOC.CH_2.CH(NH_2).COOH.$
Glutamic acid,
$HOOC.CH_2.CH_2.CH(NH_2).COOH.$

3. *Hydroxy-amino-acids.*

Serine,
$CH_2OH.CH(NH_2).COOH.$
Hydroxyglutamic acid,
$HOOC.CH_2.CHOH.CH(NH_2).COOH.$

4. *Heterocyclic Acids.*

Proline,

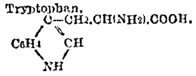
Hydroxyproline,

5. *Mono-amino-acids with Aromatic Nucleus.*

Phenylalanine,
$C_6H_5.CH_2.CH(NH_2).COOH.$
Tyrosine,
$HO.C_6H_4.CH_2.CH(NH_2).COOH.$

6. *Mono-amino-acid with Indole Nucleus.*

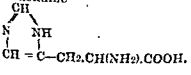
Tryptophan,



7. *Hexone Bases, or Di-amino-acids.*

Lysine,
$H_2N.CH_2.CH_2.CH_2.CH_2.CH(NH_2).COOH.$
Arginine,

Histidine



8. *Thio-amino-acid.*

Cystine,
$HOOC.CH(NH_2).CH_2S-SCH_2.CH(NH_2).COOH.$

Chemical Analysis of the Proteins.

The chemical analysis of the proteins shows that the various proteins yield different amounts of the amino-acids. Some of the data are shown in Table I. The chief peculiarity is pointed out by using italic figures. *In general,* the albumin group of proteins contains all the amino-acids, except glycine, in various proportions. The globulin group is similar, but contains glycine and has in addition a higher amount of glutamic acid, especially those globulins of vegetable origin. The phosphoproteins resemble the albumins, with no striking preponderance of any single amino-acid. The gliadin group of cereal proteins is peculiar in its high content of glutamic acid and proline. The members of the scleroprotein group (horn, hair, gelatin) are heterogeneous; and here we may note that *silk fibroin* is composed mainly of three mono-amino-acids and is the very antithesis of sturin (the protein of fish sperm), which is made up of the three hexone bases, with no or very little mono-amino-acids. Gelatin lacks cystine, tyrosine, and tryptophan. Hair is richest in cystine. These are simply some of the most obvious differences. Proteins thus differ markedly in quality.

Our analytical data are far from complete: *in no case do* the totals of the amino-acids add up to 100. The incompleteness is chiefly due to the great difficulty of separating and estimating the individual amino-acids. *There may be still* some unknown amino-acids in small quantities: hydroxyglutamic acid has been discovered recently by Dakin by a *new extraction method*, which may yet lead to further results; once again it has proved that every new process in connexion with the chemistry of the proteins has given a valuable result. Rather too much stress has been laid upon the analytical figures. The methods hardly give exactness as far as the decimal figure, and it would have been better if the data had been returned to the nearest whole number. *Many workers still give their data to two places of decimals,* so that an entirely wrong impression is given of the accuracy of the method. Fischer pointed out that his method was not quantitative, but others have neglected this important statement.

The figures for the hexone bases are more accurate; it is still not sufficient to express results *to two decimal places.* Kossel considers that *the hexone bases form a special* nucleus on account of their presence in all proteins. We might value a protein by its content of hexone bases, but it is not sufficient because their total only tells us about a *third or less of the whole molecule. Tryptophan, discovered* by Hopkins and Cole, is perhaps the most important unit in the protein molecule. It is not estimated except by direct isolation, a method which is laborious and requires considerable skill. Its amount is not known except in casein and a few other proteins. By its distinctive colour reaction with glyoxylic and sulphuric acids, it can readily be proved *to be a constituent of most proteins. The amount of* cystine in proteins is only known in a few cases, but its amount can be gauged by the sulphur content of the protein. It is the one unit known which contains sulphur, but there are indications that there is another sulphur-containing unit.

The differences in proteins are not confined to such *quantitative data; they are still more involved. Fischer's* synthetical work with the amino-acids has proved that they are combined together in a polypeptide form—i.e., the amino group of one amino-acid is combined with the carboxyl group of another, the amino group of this acid being united with the carboxyl group of still another. We therefore consider a protein molecule to be a chain of amino-acids, thus:

$$HN.CH.CO-NH.CH(CH_3).CO-HN.CH(C_4H_7).CO-HN.CH(C_6H_5).CO,$$

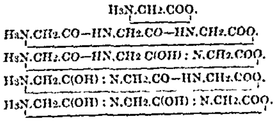
This method of combination allows theoretically of endless variation. If we take three amino-acids we can arrange them in six different ways—

glycyl-alanyl-tyrosine alanyl-glycyl-tyrosine tyrosyl-glycyl-alanine
glycyl-tyrosyl-alanine alanyl-tyrosyl-glycine tyrosyl-alanyl-glycine

With 18 or 20 amino-acids the number of arrangements is almost infinite. Differences in arrangement may be the cause of differences in proteins. Two proteins may, perhaps, have exactly similar amounts of amino-acids and yet be different. The interchange of one amino-acid would express a difference. We may imagine the proteins of the blood or milk of different species to differ in the arrangements of the units. The one may have the arrangement such as a-b-c-d-e-f, the other d-a-b-f-e-c.

Another important difference may be in the so-called tautomerism of the amino-acids and polypeptides. With the same arrangement of the amino-acids we may have several formulæ representing the polypeptide structure:—

$$H_2N.CH_2.COOH.$$
$$H_2N.CH_2.CO-HN.CH_2.CO-HN.CH_2.COOH.$$
$$H_2N.CH_2.CO-HN.CH_2.C(OH):N.CH_2.COOH.$$
$$H_2N.CH_2.C(OH):N.CH_2.CO-HN.CH_2.COOH.$$
$$H_2N.CH_2.C(OH):N.CH_2.C(OH):N.CH_2.COOH.$$



$$H_3\underbracket{N.CH_2.COO}.$$
$$H_3\underbracket{N.CH_2.CO-HN.CH_2.CO-HN.CH_2.COO}.$$
$$H_3\underbracket{N.CH_2.CO-HN.CH_2C(OH):N.CH_2.COO}.$$
$$H_3\underbracket{N.CH_2.C(OH):N.CH_2.CO-HN.CH_2.COO}.$$
$$H_3\underbracket{N.CH_2.C(OH):N.CH_2.C(OH):N.CH_2.COO}.$$

Certain of the properties of the polypeptides can be explained on this basis.

Digestion and Assimilation of Protein.

Fischer's and Kossel's work has revolutionised our conception of protein nutrition. We no longer think, like Liebig and later investigators, that the protein of the food becomes directly the protein of the body, for it has been demonstrated by the physiologists that the protein of the food undergoes hydrolysis during digestion to amino-acids, that the amino-acids circulate in the blood, and that the tissues receive amino-acids from which they build up their protein. Proteins must be regarded as a mixture of amino-acids.

---

[1] Being an abstract of a lecture delivered to the Royal Institution on April 8th, 1921.

We can look upon a protein as we look upon the contents of a box of assorted biscuits, arranged in rows and in layers of various kinds. Each biscuit should be connected to its neighbour so that we have a continuous chain. The general appearance of the contents of two boxes is different: in one box we may find sugary biscuits on the top, in another plain ones.

In the process of digestion the protein is acted upon by acid in the stomach with the formation of metaprotein. No great chemical change occurs, but we can imagine that the change consists in a tautomeric rearrangement in preparation for the action of the pepsin. Pepsin hydrolyses the protein at certain junctions, forming proteoses and peptones. Their formation can be compared to the separation of the layers of the biscuits. Pancreatic and the further digestion which follow in the intestine separate the individual amino-acids or biscuits entirely. The separate parts circulate to the tissues; the tissues select the ones they require and form another arrangement of the units, or simply replace those which have been used in their metabolism. Digestion and metabolism are a sort of reshuffling of the units. In the absence of any particular unit the tissue can no longer rebuild its substance, and consequently suffers. The old example of the inadequacy of gelatin is now explained. The tissues require tryptophan, tyrosine, and cystine; gelatin cannot provide them.

TABLE I.

—	Ox-muscle protein.	Casein.	Lact-albumin.	Gelatin.	Wheat gliadin.	Wheat glutenin.	Maize zein.	Maize glutenin.	Edestin.	Sturin.
Glycine	2·1	0	0	*19·3*	0	0·9	0	0·3	3·8

Total	67·5	66·5	57·0	65·4	83·0	59·72	85·4	45·7	81·9	83·1

In nutrition there are essentially two problems to study—the formation of new tissue, as in the growth of young animals, and the maintenance of tissue, which undergoes so-called wear and tear, in adult animals. In the latter case we have ultimately to ascertain if every unit of the molecule breaks down, or certain selected units only. If these are in the middle of a chain it would follow that the whole molecule would undergo metabolism and not units at the ends alone. The problem resolves itself into ascertaining the function of each amino-acid.

Experiments on Animals.

Since the practical difficulties of feeding animals with a mixture of pure amino-acids are far too great, advantage may be taken of feeding incomplete proteins and adding to them the missing unit or units. Wilcock and Hopkins made the first experiment of this kind in 1906. They selected zein as protein and fed it to mice, in one set alone, in another set with the addition of 2 per cent. of its amount of tryptophan. Young mice on zein alone immediately began to lose weight and generally died in 16 days; decline in weight also occurred in the other set, but with the added tryptophan death did not occur till the thirtieth day. Adult mice lived 27 days without tryptophan, 49 days with tryptophan. Tryptophan had thus an appreciable effect on the survival period of the animals. Zein is incomplete in [illegible] of other units, and death was probably on this [illegible]nt. The experiment was repeated in 1916 by Ackroyd [illegible]opkins under different but better conditions. The [illegible]ls were first given a mixture of amino-acids from casein (i.e., without tryptophan, which is destroyed in hydrolysis by acid) to which tryptophan was added; on the twelfth day the tryptophan was omitted, and included once more on the thirty-fifth day. There was growth during the first period, decline in weight during the second period, followed by growth on inclusion once more of the tryptophan.

Similar experiments have been made by Osborne and Mendel in America. They used gliadin of wheat as protein. This protein is a complete one, but it contains very little of certain amino-acids, especially lysine. Adult rats were maintained for quite long periods—as long as 500 days—but young rats capable of growth, though maintained for long periods, failed to grow. We may here notice that though the growth of the animal may be suppressed and it reaches maturity in age, the capacity to grow is not lost. Osborne and Mendel illustrated this by a photograph of a rat which had failed to grow for 273 days, but resumed growth on being given a suitable diet. The small amount of lysine in gliadin led the authors to regard this unit as essential for growth. In a later experiment they added lysine at intervals; growth occurred with the lysine, but not without it. The effect of lysine on growth was again demonstrated by Buckner, Nollau, and Kastle in the case of chickens living under the natural conditions of a poultry-farm. The birds were fed upon grain mixtures of high and low lysine content. As their photographs showed, more rapid growth took place on the mixture of high lysine content.

The element sulphur is present in proteins in the form of cystine, though, as before mentioned, another sulphur-containing unit is possibly present. Little or no cystine in a protein has also an effect upon the growth of rats. This has been most clearly demonstrated in the case of the protein, phaseolin, of the navy bean. There was slow growth with this protein, but normal growth if the protein were supplemented with 2 per cent. of its amount of cystine. Casein is deficient in cystine. Less casein is required in a diet for producing normal growth if extra cystine be included. 15 per cent. casein was required by itself, but only 9 per cent. if cystine were added. The amino-acids containing aromatic nuclei are probably essential units of the protein; but it is difficult to carry out a decisive experiment, since all proteins contain phenylalanine, though they may lack tyrosine. There is plenty of evidence that phenylalanine can be transformed in the body by oxidation; both tyrosine and phenylalanine yield homogentisic acid in cases of alkaptonuria. Totani has shown that the almost complete removal of tyrosine from the mixture of units yielded by casein made no difference to the growth of rats. There was evidently enough phenylalanine for all purposes.

The two hexone bases—arginine and histidine—as shown by Ackroyd and Hopkins, are inter-related in nutrition. Absence of both causes loss of weight; absence of either alone lessens the rate of growth. These two workers further showed that these amino-acids are connected with the production of the purine ring in the animal body—i.e., with the production of uric acid.

The function of the whole group of mono-amino-acids has yet to be determined. Are they all necessary? Of glycine we can say that it is not essential as it is the only amino-acid which the animal can synthesise. These results remind us of the well-known experiments on the need by plants of all the inorganic elements. Sir Daniel Hall, in his book on Fertilisers and Manures, gave a striking picture of barley grains grown on a full food and foods lacking one constituent. We may thus correlate the amino-acid content of proteins for growth of animals with the set of inorganic elements needed for the growth of plants.

Relative Value of Proteins in Food.

The relative value of various proteins in nutrition has been studied by Osborne and Mendel. In their experience lactalbumin is superior to casein and casein to edestin. They found that 50 per cent. more casein and 90 per cent. more edestin were required to produce the same gain in weight; in other terms, a food containing 9 per cent. lactalbumin was equal to one with 12 per cent. casein and 15 per cent. edestin.

Suitable mixtures of proteins have also been tested, and attempts are being made to find out the most suitable addenda for making the proteins of cereals more adequate for the growth of animals—that is, adding what we may call "good" protein to "bad" protein to make the latter efficient as food. Leaf and seed proteins are good as a mixture. Economically, it may be better to use an expensive protein as food for animals and produce rapid growth than to feed for longer periods on poor proteins and get slower growth. A simple calculation brings out the problem to be solved. We may wish to build up the casein of milk with 16 per cent. of glutamic acid, and we are provided with wheat gliadin with over 40 per cent. of this unit. There is waste of glutamic acid. Gliadin further contains 0·2 per cent. of lysine, whilst casein contains 6 per cent. To produce this amount we require 30 times as much gliadin, and consequently the waste of glutamic is further increased. Cannibalism is the most economical method of protein nutrition, as the amino-acids of the food are in the exact proportion required by the tissues. The nearest parallel to this is the nursing of the young animal by its mother. The child actually gets the proteins of the mammary glands.

Quality of Proteins and Causation of Pellagra.

Recent work shows that quality of protein is most probably the primary cause of pellagra, although there are some indications that general insufficiency of protein, together with improper salt supply, are contributory factors. Pellagra is a peculiar disease characterised by severe disturbance of the whole digestive tract, by skin lesions, usually bilaterally symmetrical and often mistaken at first for sunburn or chapping of the hands, face, and neck, and other exposed areas. The nervous system is also affected. There is no definite record of pellagra in Europe before maize was introduced into Spain by Columbus. From Spain the disease spread to France, Lombardy, and eastwards, wherever maize was extensively used for food in the poorer agricultural districts. The relation of maize to the disease puzzled the medical profession for nearly 200 years, as the disease occurred where maize was not used; and in some districts maize was used, but there was no pellagra. Roussel in 1866 showed that it could be cured by good food, and Lorentz (1914) and Willets (1915) successfully treated advanced cases with a generous diet. Goldberger also cured and prevented the seasonal appearance of pellagra in lunatic asylums and orphanages by increasing the quantity of meat and milk; previously the diet had been deficient in this respect. Goldberger, by the offer of a free pardon from the Governor of Mississippi, was enabled to obtain 11 convicts as volunteers for a feeding experiment to determine if pellagra could be produced by an unbalanced diet in healthy white men. The "pellagra squad," as they were called, were fed on white wheat flour, various maize preparations, polished rice, sugar, sweet potatoes, pork fat, cabbage, and turnip tops. The food had an energy value of 2950 calories and was amply sufficient in this respect. After the second month on this diet the men complained of weakness, headache, abdominal pain, and other minor discomforts. After five months six developed a rash, which was pronounced by experts to be identical with that seen in pellagra. During the last four weeks all the prisoners had shown marked loss of weight and were much out of health. Pellagra would probably have developed in the remainder, but the experiment had to be abandoned owing to the refusal of the men to continue. A control was carried out at the same time; their diet contained some meat, eggs, and butter-milk; there was not a single case of pellagra and no progressive loss of body-weight.

These and other facts clearly point to the diet as the controlling factor in the cause and prevention of the disease. The determining factor seems to be the quality of the protein. Good evidence on this point has been furnished by Wilson of Cairo. In 1916 pellagra broke out in a camp for Armenian refugees at Port Said. Wilson showed that the diet at first supplied was inadequate both in energy supply (2200 calories) and in protein supply; 92 per cent. of the protein was of vegetable origin, three-quarters from wheat and one-quarter from maize. By determining the least daily amount of a protein required to keep a man from loss of body protein Thomas was able to assign a series of values to proteins representing their biological efficiency. The comparative values according to the quantity required to maintain a man without loss of nitrogen and body-weight were:—

Ox meat...	104	Casein	70	Peas	56
Cow's milk	100	Rice	83	Wheat-flour ...	40
Fish...	95	Potato	79	Maize meal... ...	30

The biological value of meat is therefore three times that of maize. Wilson calculated that the diet as given to the refugees was equal to 22 g. of casein. On improvement to a casein equivalent of 41 g. no more cases of pellagra occurred.

Chick and Hume (1920) succeeded in producing in three monkeys symptoms very like those of human pellagra. The diet was very carefully selected, and was deficient only in respect that it contained no animal protein. One monkey refused the food after a short time; he lost weight and showed signs of incipient pellagra. The second monkey also lost weight, but the loss was lessened by adding tryptophan; but other amino-acids lacking in maize had no appreciable effect. This monkey had signs of pellagra and was cured by giving a normal diet. The third monkey had its loss of weight arrested by including tryptophan and hexone bases; it showed some of the characteristic symptoms of pellagra, such as the symmetrical bilateral rash. It appears thus that pellagra is caused by a continuous shortage in the supply of certain amino-acids in the food.

A diet containing animal protein in small quantities will supply the needful amino-acids; a large supply of vegetable protein may not contain the needful amino-acids.

PRUSSIC ACID AS INSECTICIDE.

DISINFECTION nowadays, and the prevention of diseases thereby, is so largely concerned with the destruction of insects—carriers of plague, typhus, and remittent fever—that we are glad to hear from Mr. Laporte,[1] the bacteriologist to the French army at Mayence, how surely and inexpensively those insects may be killed by hydrocyanic acid. The method was, he tells us, first used in America to destroy the insect parasites of fruit trees; each tree being enclosed in a tent, hydrocyanic acid was evolved within, and next morning the pests would be dead. Hydrocyanic acid is produced by the action of cyanide of sodium on dilute sulphuric acid. It is a 1 per cent. atmosphere that is aimed at; the gas is light and diffuses itself rapidly, so every door and window must be closed and all cracks as usual covered up with pasted paper. To produce a 1 per cent. atmosphere in a room of 3500 cubic feet there must be a large tub containing 1¾ gallons of water, best at a temperature of 50° F., into which are poured 12 lb. of sulphuric acid, sp. gr. 1·7, and beside it is laid 6 lb. of sodic cyanide wrapped up in thick paper. When the process is to be set going, the operator, carrying a machine to give him oxygen, drops the parcel into the dilute sulphuric acid, and then flies for the door, which is closed after him and sealed from outside, and is not opened for 18–24 hours, when the windows, too, are opened, and the gas is quickly blown out. Cellars require to be cleared out with a fan-draught. Then 10 oz. of slaked lime are put in the tub, and the neutralised poisonous liquid is poured into a pit in the ground, dug previously. After hydrocyanic acid gas disinfection in some places larvæ, pupæ, and imagines may be swept up in quantities. This disinfection is thought to be particularly effective in dealing with parasites of plants, or with weevils and beetles in flour-mills, with lice (insect and eggs both killed in two hours), fleas, bed-bugs, moths (that eat clothes), mosquitoes, rats, and mice. Foodstuffs cannot be left in the area, for they absorb and retain the gas unequally, but flour can be dealt with, and nothing else is damaged. One very useful application enabled 2000 men to be deloused daily at Metz—300 men in each of seven groups whose clothing occupied the disinfector for precisely 2¼ hours. There is no fear of damage to boots, furs, textile materials, or metals, the cost of materials is small, the personnel required is few but highly trained. The German Government refuses to allow private persons to use this disinfection, but a company exists to carry it out, a company which seems to be one with the Government and has practically a monopoly. This method of disinfection was employed by Germany in the war for killing rats and insects in submarines and small merchant ships.

Four or five years ago Surgeon R. H. Creel, of the U.S. Public Health Service, in discussing quarantine methods, went fully into the employment of hydrocyanic acid for disinfection.[2] He gave the duration of exposure necessary to kill mosquitoes, fleas, bed-bugs, rats, cockroaches, and lice, and grimly recorded the death of one stowaway.

THE BUFF BOOK AGAIN.

THE second edition of this "classified commercial telephone directory for London," recently issued "with the authority and coöperation of H.M. Postmaster-General," has a guaranteed minimum circulation of 150,000 copies. This issue contains medical names under the following headings:—

Class.	Number of names.	Class.	Number of names.
Cardiologist	1	Physicians (consulting) ...	3
Laryngologist, aurist, and rhinologist...	1	Surgeons	10
Physicians and surgeons ...	72	Surgeons (consulting) ...	1

There may be other solo groups which we have failed to find. No heading of General practitioners is given. Fifteen dental surgeons appear and six dentists, all of whose names appear on the Dental Register. Names of other dental practitioners are given under the heading Dentistry. A number of dental surgeons have paid extra for large type, and two medical specialists have apparently done so. The publisher has, however, made an attempt to bring the Directory within the ethical standard laid down by the General Medical Council (see THE LANCET, March 19th, p. 608) by inserting the following prefatory notice:—

> In order to increase the utility of "the Buff Book" the Proprietors have decided to include, under any one heading, in small type, *free of charge*, the names of all Traders who will fill up and return the Order Form which will be found at the end of the Book.

This seems to entitle any doctor who is content to describe himself as a trader to appear in the classified directory gratis under one heading, and removes any advantage to be gained from the payment of a guinea. Should the General Medical Council consider this free from objection it wou be simple to transfer en bloc the names of telephone subscribers in the London section of the Medical Directory. In passing it may be remarked that the convenience of insertion in the Buff Book to subscribers now on the Langham Exchange is mitigated by the fact that their numbers appear wrongly in the Buff Book, whereas they appear correctly in the new issue of the official Telephone Directory.

LYSOL AS A GARGLE.

To the Editor of THE LANCET.

SIR,—Our attention has been drawn to the report of an inquest held by the Fulham coroner upon a woman who was held to have died as a result of using a solution of lysol as a gargle. So far as our records show, no fatality has yet been recorded caused by swallowing lysol in diluted form. It has been proved that lysol is only one-eighth as poisonous as carbolic, but it does not follow that toxic results may follow the size of the dose. In the case above mentioned the quantity swallowed is not indicated; we should surmise it was not very large and apparently it was diluted. Recovery has been reported in two cases where the quantity taken exceeded three ounces undiluted.

The following extract from a letter received just recently may be of interest to your readers: "I have recently undergone a rather serious operation for cancer of the breast, and since then have been taking about 14 drops of lysol in a small tumbler of lukewarm water; this I have done for twice a day for about a month."

We are, Sir, yours faithfully,

April 25th, 1921. LYSOL, LIMITED.

THE BLOOD PRESSURE IN MENSTRUATION.

To the Editor of THE LANCET.

SIR,—I should be greatly obliged if you or one of your correspondents could direct me where to find some full information as to the changes in the blood pressure in women during menstruation. I seem to have heard that the pressure rises during a week or so preceding the commencement of menstruation, that as soon as the flow begins the pressure commences to fall, and that at the end of the three or four days during which it lasts the pressure is below the ordinary blood pressure of the woman. If these statements are true, estimations of the blood pressure in women lose much of their value unless the relation of the observation to the catamenia is known.

I am, Sir, yours faithfully,

April 19th, 1921. F.R.C.S.

BURGLARIES IN FLATS.

PARAGRAPHS in the newspapers stated recently that a flat in London, the residence of a medical practitioner, had been entered at night and robbed by burglars who were said to have forced open the front door. No further particulars have been given and there is no mention of the thieves having been caught, but as a certain number of members of the medical profession live now in flats and many of them are absent, at their consulting rooms, during the day, it may not be out of place to indicate the conditions which render flats easy to enter by night or day by any thief who takes the risk of being intercepted by the hall porter. In the first place, by day flats are often left empty, either because no servants are kept or because they are allowed to go out when their employers also are absent. Flats are also left empty when their occupants go away for a holiday, the fact of a porter living on the premises being considered to be a sufficient protection. That they are thus left unprotected may become known to thieves by the collusion of servants and in various other ways, or a man who has sufficient audacity and thinks that the coast is probably clear walks boldly upstairs, ready to deliver an imaginary message, and knocks and rings until he is sure that there is no occupant to interfere with him. Having got so far he is fairly safe, but only if he can enter without making enough noise to disturb the dwellers above or below, and without doing enough damage to attract immediate attention if any one should pass the door. He also has, of course, to take his chance of some inmate of the flat coming home. Probably, however, as has been suggested, the thief ascertains the habits of his victim (male or female) and of the servants, if any, before he commences his enterprise. The principal point in his favour, however, lies in the ease with which a large number of flats can be entered, owing to the unsubstantial nature of their front doors. These in a great number of cases have upper panels of glass and not of plate glass, but of small panes of coloured glass joined together by "leading." Everyone can see how quickly one or o such panes can be taken out without any great skill the part of the house-breaker, and how easily he can pass his hand through, turn the handle, and enter. He ake practically no noise in doing this, so that it is not impossible for him to do it safely at night with someone actually at home at the time; and he can replace the glass so that his interference is not likely to be noticed during his visit. There is, at least, one precaution open to the flat-dweller, and one not often taken owing to the prejudice against carrying the rather large latch-key required. Anyone who lives in a flat will do well to consider the advisability of seeing that his front door is fitted with a strong lock capable of being "double locked" from outside or inside. The same applies to many small houses. By double locking is meant the extra turn of the key which renders the handle impossible to turn until the key has been used again to release it. When the lock is good, forcing open with a "jemmy" or making a hole in a panel large enough to admit a man's body will make so much noise and render the breaking-in so conspicuous that neither is likely to be attempted.

THE EFFECT OF THE COAL CRISIS ON ATMOSPHERE.

Mr. W. Thomson, chairman of Manchester and Salford Sanitary Association, by means of a special recording instrument, has studied the atmospheric impurities during the coal crisis, and compared his results with those obtained when domestic fires and works' chimmeys are in full blast. The difference is most striking. Under normal conditions—i.e., no coal strike—the particulate mechanical impurities are most abundant on Monday and Tuesday, and smallest in amount on Sundays, when factories and city offices are inactive. Under present conditions everyone is struck by the obvious improvement of the atmosphere, of the visibility, and the increased supply of the sun's rays—a striking confirmation, if such be needed—of the maleficent effects of a smoky atmosphere.

THE INSCRIPTION ON GUY'S HOSPITAL WAR MEMORIAL.

IN the editorial and correspondence columns of *Guy's Hospital Gazette* recently the question of a suitable incription for the arch which is being erected as a war memorial has been freely discussed. The final decision of the War Memorial Committee is that on the outside of the arch should be the words, "Erected by the friends of 110 Guy's men who gave their lives in the Great War," and on the inside the inscription:—

"To the honour of those who came through,
To the memory of those who died.
1914-1919."

In addition, over each panel bearing the names of those who died, should be the words, "In Memoriam."

Objection has been taken in certain quarters to these words on the grounds that those who came through alive merely did their duty, and that sacrifice only should be memorialised. But it should not be forgotten that some medical students—for example, those who broke away in the middle of their studies to be naval surgeon-probationers —sacrificed not only time but the effects of practice and settlement, regarded as important by our modern psychologists, to such an extent as to affect their whole future careers. Others sacrificed limbs, others mental stability. It is a question of degree rather than of kind.

PUBLIC HEALTH OF MAURITIUS.

ACCORDING to a report prepared by Mr. L. Kœnig, Assistant Colonial Secretary, the birth-rate in 1919 was 35·2 and the death-rate 64·9 per 1000. The population on Dec. 31st of the same year was estimated at 364,493. The abnormal mortality was attributable to a violent outbreak of influenza which prevailed in the island in the months of May, June, and July; it is believed that the deaths from this epidemic numbered more than 11,000. The mortality was especially high in Port Louis and was chiefly due to the poverty and decreased power of resistance of the people. Malaria continues to take a large toll of human life and a still larger toll of health and capacity. Increased attention is being devoted to measures of prevention and no expense is being spared. Phthisis and other forms of tuberculosis appear to be on the increase. In the public general hospitals there are altogether 975 beds. During 1919 25,073 patients were treated, and the deaths in hospitals numbered 1905. Attendance was given in the public dispensaries to 78,546 patients. In the St. Lazare Leper Asylum there were 67 inmates on Dec. 31st, 1918, and 14 were admitted during 1919; 2 patients absconded, 8 were discharged, and 19 died. Mauritius has a warm climate, but is seldom too hot for comfort. The temperature even during the warm season is never excessive, and during the winter months from May to September the climate in the elevated plateau is often bracing and generally delightfully cool.

The Goulstonian Lectures

ON

GLYCÆMIA AND GLYCOSURIA.

Delivered before the Royal College of Physicians of London on March 1st, 1921,

BY GEORGE GRAHAM, M.A., M.D. CANTAB., F.R.C.P. LOND.,

SECOND ASSISTANT, MEDICAL CLINIC, ST. BARTHOLOMEW'S HOSPITAL; ASSISTANT PHYSICIAN, GREAT NORTHERN CENTRAL HOSPITAL.

LECTURE I.

I WISH, first of all, to express my thanks to the Royal College of Physicians for the great honour which it has done me in selecting me to be Goulstonian lecturer for this year. Secondly, I wish to commemorate the name of Theodore Goulston, a Fellow of this College, who in 1632 bequeathed some property in Essex in order to found this lectureship. The first lecture was given in 1639, and, except for a few breaks owing to wars and other causes, it has been given annually since that time. When Dr. Goulston died in 1632 the study of diabetes was still in its infancy, as Thomas Willis was then only a boy of 12, and it was not until 1674 that he observed that the urine of diabetic patients had a sweet taste. Willis was not the Goulstonian lecturer, and, as far as I can ascertain, diabetes has only been the subject of these lectures on three occasions—by Dr. F. W. Pavy in 1863, by Dr. W. C. Bosanquet in 1905, and by Dr. E. P. Poulton in 1918.

Although it is only three years since my friend and co-worker on other subjects, Dr. Poulton, was Goulstonian lecturer, I do not feel that I owe you any apology for talking about diabetes again, as Dr. Poulton was chiefly concerned with the questions of acidosis and ketosis, while I shall approach the subject by considering the fate of the sugar which is present in the blood. In the second lecture I shall speak of the different types of diabetes, and in the third describe the principles on which the modern treatment is based.

THE FATE OF THE SUGAR PRESENT IN THE BLOOD.

The presence of sugar in the blood was demonstrated by Claude Bernard, and the amount of sugar which is normally present in the blood has been estimated by many observers and by many methods. Pavy's statement,[1] that for animals, dogs, &c., the usual amount varied from "0·06 to 0·10 g. or a little more" has been substantiated by recent workers using much simpler methods. The figure given for the amount which is usually present in the healthy fasting adult is 0·08 to 0·12 g. per cent.

One great question which concerned Pavy[2] was why this sugar was not excreted in the urine. He showed that as a matter of fact sugar was excreted in the urine of all healthy adults in very small amounts. He estimated that it was present in a concentration of less than 0·03 per cent. Such an amount is not sufficient to give a positive result with Fehling's solution or with Benedict's solution, as the latter only gives a positive result in a concentration of 0·08 per cent. Recently Benedict and Osterberg[3] have found that sugar is always present in the urine in small amounts up to 0·01 per cent. In two cases which were very carefully investigated the total amounts excreted were 1 g. and 0·5 g. per day. Pavy sought to explain the absence of sugar in the urine in appreciable amounts by supposing that the sugar was carried by the leucocytes. Others have supposed that the sugar was present in a colloidal combination and not as a crystalloid.

In 1903 Michaelis and Rona[4] found that the sugar could be diffused away from the cells and that the sugar must be in a state of solution. This was confirmed in 1914 by Abel, Rowntree, and Turner,[5] who showed that if the blood was allowed to circulate through a celloidin tube inserted into the general circulation of the animal the sugar diffused out from the blood into the fluid surrounding the celloidin tube. The sugar is therefore present in the blood as a crystalloid.

Until 1903 it was accepted that sugar was present in the plasma and not in the corpuscles, but in that year Michaelis and Rona,[6] working on dogs, found that the sugar was shared in unequal and inconstant amounts between the corpuscles and plasma. They repeated and extended their observations, which were confirmed by all other workers on this subject except Lyttgens and Sandgren[7] and Bang.[8] Bang and his pupils were unable to prepare an osazone from the corpuscles and challenged Michaelis and Rona to prepare one. It was also very extraordinary that in some animals—the dog, cat, and man—the sugar was apparently shared between the corpuscles and plasma, while in the rabbit it was all in the plasma.

In 1919 Falta and Richter Quittner[9] re-investigated the question and found that if they prevented coagulation of the blood by the addition of hirudin all the sugar was present in the plasma. If, however, other methods preventing coagulation were used—e.g., the addition of potassium oxalate or sodium citrate—or if the blood was defibrinated, the sugar was shared between the corpuscles and plasma. Falta found that this was true of the blood of all the usual laboratory animals. Confirmation of this work is forthcoming in the independent work of Brinkman and V. Davis,[10][11] which was published almost simultaneously. Brinkman was working on frog's blood, and with the use of hirudin he found that the sugar was always present in the plasma. When he extended his work to human blood he was not so successful as the hirudin he was using did not completely prevent the onset of coagulation. If any strands of fibrin were present the corpuscles contained sugar. However, by chilling the blood and bubbling an indifferent gas through the blood he was able to prevent any coagulation taking place and to demonstrate that all the sugar was present in the plasma.

The Hæmatocrit Method.

These observations are of great importance in the estimation of the sugar in the blood. The amount of sugar is always given in grammes per 100 c.cm. or per 100 g. of blood. But if the sugar is only present in the plasma this mode of presentation may be very misleading, as Falta points out, unless a simultaneous estimation is made of the respective volumes of plasma and corpuscles by the hæmatocrit method. This observation may affect the accuracy of determinations which are made from the blood obtained by pricking the finger when any squeezing is necessary to obtain the blood. It can be overcome by (1) warming the hand in hot water beforehand; (2) always pricking the finger deeply; and (3) correcting the result by doing a hæmatocrit determination. Unfortunately hirudin is unobtainable at present, and potassium oxalate must therefore be used instead in making the hæmatocrit determinations. A correction of 1–2 per cent. must be made, as the potassium oxalate gives too low a reading for the volume of the cells.

I have recently compared the blood from the vein with that obtained from the finger with the help of Dr. A. E. Gow. The figures for the red cells lay within the limits of experimental error, those for the hæmatocrit were identical, the figures for the blood sugar lay within the limits of experimental error. There is, therefore, no appreciable error in collecting blood from the finger. A more serious source of error may be variations in the volume of cells and plasma. Eppstein[12] found that the volume of plasma and corpuscles was not a constant one as it varied after a meal. He always made a hæmatocrit determination in order to correct for this variation. Recently Dreyer, Bazett, and Pierce[13] have shown that the proportion of plasma and corpuscles varies in a surprising way and makes it still more necessary to check the results with a hæmatocrit determination. The diurnal variations may be as much as 30 per cent., and a 10 per cent. change is quite common. The changes did not seem to bear any relation to meals.

The Nature of the Filter.

The mechanism by which the sugar is prevented from being excreted by the kidney still remains unexplained. According to Cushny's view of kidney functions, the sugar is passively filtered off from the blood together with the other constituents of the urine, and is reabsorbed lower down in the kidney tubules. On this hypothesis a great deal of work has to be done by the kidney in reabsorbing these substances, and as in some cases of diabetes, of which I shall speak later, the level of the blood sugar may rise to 0.30 g. per cent. without any sugar being excreted in the urine, the kidney must do a great deal of extra work.

Hamburger and Brinkman[14] have done some suggestive work on this point. They found that when they perfused the frog's kidney with ordinary Ringer's solution containing glucose all the sugar was excreted in the urine. By varying the potassium and calcium in the solution the excretion of the sugar ceased to be a quantitative one. By making the H.-ion concentration of the perfusing fluid correspond with that of frog's blood they found that the kidney did not allow any sugar to pass even if the concentration was over 0·10 per cent. The addition of lactose to the perfusing fluid was always followed by the excretion of lactose in the urine, although no glucose was excreted. These experiments at present lack confirmation, and the possibilities of error have not been exhaustively excluded, but they do offer an explanation of the different levels of the leak-point for sugar in human beings, to which I shall refer later.

Pavy[15] and all other workers on this subject up to 1911 believed that there was no increase of sugar in the blood after a heavy carbohydrate meal. It was believed that the liver was the organ which prevented the sugar from increasing in the general circulation. Pavy thought that if the liver failed to do its duty and allowed an increase of sugar in the blood, the sugar would instantly be excreted in the urine.

In 1911 Baudouin[16] examined his patients one hour after a meal and found that there was a slight increase in the amount of sugar. Frank,[17] Reicher and Stern[18] confirmed and slightly extended his observation. A. Th. B. Jacobsen[19] in 1913 pointed out that the rise in the blood sugar occurred much earlier than one hour, and might be present within five minutes of a dose of sugar. It usually reached its maximum 15–30 minutes after the sugar, and in 7 cases was back at its original level after 60 minutes. In 7 cases the fasting value was not reached until two to three hours afterwards. In 7 cases sugar was excreted, but the greatest amount excreted was 1·38 g. These observations have been confirmed by Bang and many others, including myself.

Variations in Individual Response to a Dose of Sugar.

The response of each individual to a dose of sugar is probably slightly different, and varies from time to time according to his state of health. I[20] have made six experiments on myself at different times, immediately before and after a holiday, and the variations are somewhat remarkable. All the estimations of the blood sugar were made by Bang's[21] method, which with slight modifications in technique I have found very satisfactory when the difficulties over the impurities of the chemicals have been surmounted. The difference between the blood curves (Figs. 1 and 2) is very striking, and makes it much easier to understand why a diabetic passes sugar when he is upset by quite trivial ailments or troubles.

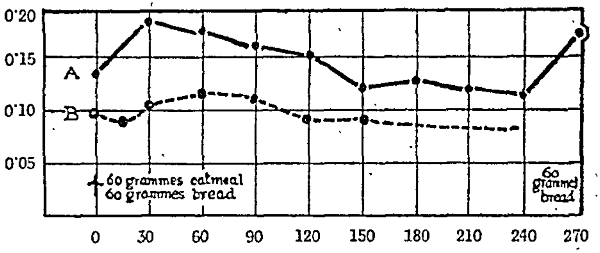
In considering the changes which take place in the percentage amount of sugar in the blood the total amount of sugar should also be considered. The volume of the blood is about $\frac{1}{13}$th of the total weight of the body, according to the recent work of Keith, Rowntree and Geraghty.[22] In the case of a man who weighs 65 kilos, or 10 st. 3 lb., the volume of the blood will be 5000 g. Since the average percentage amount of sugar in the blood is about 0·10 g. per 100 g. blood the total sugar circulating in the blood is 5 g. An increase in the blood sugar from 0·10 g. to 0·20 g. would mean that an extra 5 g. was circulating in the blood. A diabetic with a blood sugar of 0·40 g. present would have an extra 15 g. of sugar in the blood. The amount of sugar which can be stored in the blood is therefore very small, and this emphasises the delicacy of the mechanism by which sugar is absorbed into the body.

The increase in the blood sugar after each meal, which contains a fair amount of carbohydrate, shows that the liver does not prevent sugar from entering the peripheral circulation, and it is of interest to consider how much sugar the hepatic veins may contain. The blood in the portal vein after a meal is rich in sugar, but in its passage through the liver it is diluted with the blood from the hepatic artery. The blood leaves the liver by the hepatic veins, which join the erior vena cava at once. The liver blood is there uted at once with the blood from the lower limbs. A ther dilution takes place almost immediately after-nls as the blood mixes in the heart with the blood the superior vena cava. It is clear that the blood in the hepatic veins must contain more sugar than the diluted blood in the peripheral circulation, but it is not possible to say how much more, as measurements of the vessels after death are difficult to do, and no account is taken of the velocity of the blood flow.

The Destination of Blood Sugar.

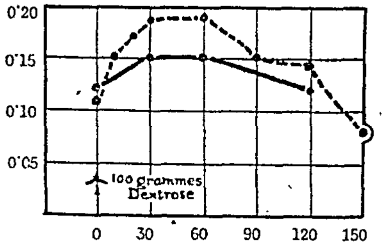
The fact that the increase in the blood sugar takes place after each carbohydrate meal which is eaten arouses interest as to the destination of this sugar. None of the sugar is excreted in the urine so long as the amount of sugar does not rise above the "leak point" for the individual, and after circulating in the blood for a variable length of time the sugar disappears from the circulation. Some of the sugar is burnt at once as the respiratory quotient rises immediately after a carbohydrate meal and remains about 1·0 for some time, and then gradually falls. The rise and fall in the blood sugar is usually over in about one hour even if 100 g. is taken at one time. If all the sugar which disappears from the circulation in the hour were burnt in that time it would mean that 400 calories had been used in one hour from carbohydrates alone. As the subject of these experiments is usually a laboratory worker, and as he sits fairly still during that period it is hardly possible that all this amount of sugar could be burnt up. Moreover, Johanson[23] has shown that the increase in the output of carbon dioxide which occurs after a dose of sugar persists for a period of five to seven hours. Hence some of the sugar must be stored elsewhere in the body—i.e., in the liver, muscles, or elsewhere.

In each of the charts the figures at the left side indicate grammes of sugar in 100 g. blood.



The figures at the foot of the chart represent minutes after meal.

FIG. 1 shows the effect of a carbohydrate meal consisting of 60 g. porridge, 60 g. bread, 150 c.cm. milk, on my blood (A) before and (B) after a holiday. Before the holiday the fasting value was 0·13 g. per cent., and 30 minutes later the sugar had increased to 0·18 per cent. The amount of sugar gradually decreased and reached 0·12 2½ hours later. After the holiday the fasting value was 0·095 g., and the rise in the blood sugar which took place ½ hour after the meal was small, and reached its maximum 0·11 g. after 1 hour. In this case the rise was 0·015, whereas before the holiday it was 0·05 g.



In Charts 2, 3, and 4 the figures at the foot represent minutes after injection of sugar.

FIG. 2 shows the effect of a dose of 100 g. of glucose six weeks and one week before another holiday. Six weeks before the holiday (continuous line) the rise in the blood sugar was 0·03 g. in 1 hour. One week before the holiday (dotted line) it was 0·07. On neither occasion when I was taking the holiday was I suffering, so far as I know, from any illness, although on each occasion I had been working long hours in the laboratories and wards.

The amount of glycogen which is stored in these places may be considerable. Thus Schöndorf[24] estimated the amount of glycogen in the muscles and liver of seven dogs. In three dogs the muscles contained more sugar than the liver; in two dogs the muscles and liver contained about the same amount of sugar; in two dogs the muscles contained less glycogen than the liver.

As the muscles contain so much glycogen it is possible that the "extra" sugar which is seen in the blood after a carbohydrate meal is on its way to the muscles. De Fillipi[25] has investigated the effect of shutting out the liver from the portal circulation by means of an Eck's fistula. He found that there was a small decrease in the tolerance for dextrose, but a larger decrease in the tolerance for lævulose.

Tolerance to Different Sugars.

Jacobsen[26] repeated these experiments on three dogs, making careful determinations of the tolerance for dextrose, lævulose, and saccharose before and after the operation.

	Before operation.	After operation.
Tolerance for—		
Dextrose ...	115 g.	80 g.
Saccharose	170 ,,	15 ,,
Lævulose ...	90 ,,	9 ,,

The decrease in the tolerance for dextrose is therefore small as compared with the decrease for lævulose.

Effect on the Liver.

De Fillipi did not make any pathological report on the state of the liver, but Jacobsen stated the liver in his dogs appeared small, hard, and tough; on microscopical section there was atrophy of the centre of the lobule and fatty degeneration. The effect of removing the liver from the portal blood flow, although it does diminish the tolerance for sugar, does not upset the metabolism as much as might be expected. Both De Fillipi and Jacobsen suggest that the muscles can assimilate the dextrose but that they cannot store the lævulose.

De Fillipi determined the amount of glycogen which was present in the liver and muscles of the Eck's fistula dogs. The figures show that the liver of the Eck's fistula dogs contain very little glycogen and resemble those for the liver of Pflüger's dog which had fasted for 28 days. The muscle contained a good deal of glycogen, and the amounts corresponded with those found in the muscles of dogs which had been well fed.

The tolerance for dextrose has been tested in diseases in which the liver has been grossly diseased, as in cirrhosis of the liver. Strauss[27] found that 90 per cent. of patients with diseases of the liver, such as cirrhosis, excrete lævulose after a dose of 100 g. of lævulose. Only 10 per cent. of healthy people excreted lævulose. The amounts of lævulose excreted are always small, usually about 1 per cent. of the dose. In acute phosphorus poisoning about 85 per cent. of the cases showed a diminished tolerance after a dose of 100 g. of sugar; the amount of dextrose excreted varied from 22 g. to mere traces.

The experiments in which the liver has been cut out of the portal circulation, and those in which the liver is seriously damaged in disease, show that the muscles play an important part in the storage of glycogen, and it is possible that the "extra sugar" in the blood after a carbohydrate meal is on its way to the muscles.

The effect of lævulose on the blood sugar in man was observed by Bergmark,[28] who found that practically no rise occurred after doses of 50 g.

This has been repeated by McLean and de Wessolow,[29] who gave similar doses. A dose of 50 g. caused a rise from 0·10 to 0·11, which is almost within the limits of experimental error. I had observed the effect of a still larger dose of lævulose, 100 g., as I have done most of my experiments on myself with that dose of dextrose. (Fig. 3.) The initial figure for the blood sugar was 0·095, and 30 minutes after the lævulose it had risen to 0·15; at the end of one hour it was still 0·145 g., at the end of two hours 0·115 g., at the end of three hours 0·125 g. At this point 100 g. of dextrose was taken; at the end of 15 minutes the sugar had risen to 0·15, at the end of 30 minutes to 0·195 g. During the first 40 minutes after the lævulose 0·15 g. of a reducing substance was excreted in the urine. This substance was lævorotatory and was probably lævulose. In the next 2 hours and 40 minutes 0·07 g. of a similar lævorotatory substance was excreted in the urine. In the hour after the dextrose no reducing substance was excreted in the urine. Using a dose of 100 g. of lævulose the rise in the blood sugar was 0.055 g. compared with the rise of 0·01 observed by Bergmark after 50 g., and is only a little smaller than the rise after the dextrose of 0·075 g. The significant point is that the lævulose was excreted, although the blood sugar was never above 0·15 g., whereas the dextrose caused a rise to 0·195 without causing any excretion of dextrose. On another occasion 100 g. of lævulose caused a similar rise and the reducing substance gave Seliwanow's test for lævulose.

Woodyat, Sansun, and Wilder[30] have also made experiments which show the difference between lævulose and dextrose.

By means of an ingenious apparatus they have injected sugar solutions continuously into veins. They were able to inject dextrose at the rate of 0·8 to 0·9 g. per kg. per hour into dogs and men without causing any glycosuria. In the case of a man of 65 kg. 52 g. of dextrose could be injected each hour. For lævulose the figures are much lower as only 0·15 g. per kg. per hour or 9·7 g. for a man of 65 kg. could be injected without causing glycosuria. The difference between the dextrose and lævulose is therefore very great, and coupled with the other work suggest that the lævulose is normally dealt with in the liver, but that if there is any appreciable escape into the peripheral blood some sugar is excreted by the kidneys. On this hypothesis lævulose occupies the position that dextrose held in the mind of Pavy.

Pavy[31] pointed out that the blood in the peripheral circulation contained very little more sugar after hydrolysis with sulphuric acid, whereas the blood in the portal vein showed a considerable increase. He considered that the liver prevented the entrance of this hydrolysable sugar into the peripheral blood. Cammidge[32] has recently confirmed these observations and he believes that this substance is similar to a dextrin.

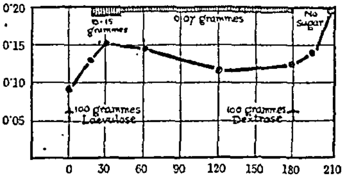


FIG. 3.—Showing the effect of 100 g. of lævulose on the level of the blood sugar, compared with the effect of 100 g. dextrose.

The especial functions of the liver seem to be: (1) preventing the hydrolysable sugar from entering the general circulation; (2) storing up the lævulose.

Ivan Bang[33] has made many experiments to try and discover the fate of the extra sugar which is seen in the blood after a carbohydrate meal. He fed rabbits with sugar and also injected sugar intravenously. The rabbits were killed half to two hours afterwards and the total amount of sugar and glycogen which was present in the body was determined. In these experiments, in which the sugar was given through a stomach tube, the total amount of sugar or glycogen found in the liver, blood, and lymph varied from 6·2 per cent., 22·9 per cent., 28·7 per cent. of the sugar which had been absorbed. After intravenous injections of sugar Bang found that although the animal was killed at once the amount of sugar in the liver immediately after the injection was only 8–12 per cent. of the injected sugar. The blood contained 7·5–11 per cent. of the injected sugar and the muscles only 5 per cent. Although Bang examined the whole body he was unable to recover more than 48–75 per cent. of the sugar which had been injected. In the experiment in which 75 per cent. was recovered, 30 per cent. of the sugar was still in the blood.

The Liver Not the Chief Storehouse for Sugar.

These experiments confirm the other experiments which I have quoted and show that the liver is not the chief storehouse for sugar in the body. The complete disappearance of 25–50 per cent. of the sugar which has been injected is most remarkable and suggests that the sugar has been converted into another compound which escapes detection.

This work has been repeated by Kleiner,[34] who found that he could not recover the sugar injected. He also injected dead animals and found that the sugar disappeared from the blood in the same way as it does in live animals. In dead animals, however, the sugar was present in the body fluids and muscles and could be recovered. In living animals he found some evidence that a condensation of the sugar took place in the muscles. The work of Cohnheim[35] on the effect of muscle juice on sugar in the presence of pancreatic juice bears on this point. He showed that if suitably prepared muscle juice was allowed to act on sugar under strictly aseptic precautions a small amount of sugar disappeared. The addition of pancreatic extract in suitabl amounts increased the effect of the muscle juice, but of pancreatic extract prevented the action. The p extract did not act like a ferment as it was not d by heating and could also be extracted with alcohol. results were contradicted by Claus and Emden, Cohnheim repeated his experiments with many precautions and obtained a similar result. These experiments have been confirmed by de Witt[37] and others, but they are especially supported by Hall's[38] work. He found that the best results were obtained when the alcoholic extract of the pancreas was used, and that 25 per cent. of the sugar might disappear. The mixture of muscle juice and pancreas extract could only act on dextrose, and could not attack arabinose, lævulose, or lactose. Levene and Meyer[39] confirmed Hall's results, and showed that the sugar which had disappeared could be recovered by boiling the mixture with hydrochloric acid for an hour. This experiment showed that the sugar had not been used but stored away. They were also able to isolate a biosazone from the mixture. Their work is good evidence that a condensation product had been formed by the interaction of the muscle juice and pancreatic extract. Cohnheim's substance must therefore be accepted as an important agent in the storage of sugar in the muscle. This work suggests that the sugar which Bang[33] was unable to recover after the injection of sugar into animals has been stored as a condensation product in the muscle.

The problem has also been investigated by perfusing the living heart muscle with solutions containing sugar. The work is difficult, as the experiments may be invalidated by the amount of glycogen which the heart muscle contains and by bacterial action, &c.

Owing to some of these causes the earlier work is unreliable, but Cruikshank and Paterson[40] were able to show that the heart of a healthy dog burnt sugar at the rate of 1·87 mg. per kg. of heart muscle, whereas the heart of the diabetic dog burnt sugar at the rate of 0·9 mg. per kg.

Starling and Lovatt Evans[41] found that the respiratory quotient of the diabetic heart was 0·71 instead of 0·85 for the healthy heart, showing that there was a depression or abolition of the power of the diabetic muscle to use carbohydrate. They found that an acid extract of the pancreas very occasionally enabled the diabetic heart to use more sugar and sent up the respiratory quotient. More recently Clark[42] has repeated this work, using special precautions to prevent the destruction of sugar by bacterial action in the perfusing fluid. He found that on perfusing the healthy heart very little sugar disappeared in the first two hours, but that in the third and fourth hours a considerable amount of sugar disappeared. If, however, the pancreas was brought into the circulation the sugar began to disappear at once. The sugar could not be recovered by heating with hydrochloric acid, as in Levine and Meyer's work. Perfusion through the pancreas did not seem to alter the sugar in any way, and it is suggested that the perfusing fluid picked up something from the pancreas which enabled the muscle to use the sugar. Since the perfusing fluid lost its power after boiling or standing it seems probable that the active substance is a ferment.

Hedon[43] made some important observations on the diabetic animal. If large amounts of healthy blood are given to a diabetic dog there is a decrease of the sugar output and a fall in the level of the blood sugar, but the effects were very transient. The effect of connecting the pancreas of a healthy dog with the peripheral circulation of the diabetic dog was next investigated, but did not cause more effect than the transfusion of blood had done. If, however, the healthy pancreas was connected with the portal circulation the results were very striking, as the glycosuria disappeared and the blood sugar decreased. These effects persisted for a little while after the transfusion had ceased. This observation suggests that the pancreatic hormone can only act if it has passed through the liver, and it is of interest to remember that all the opposing group of glands discharge into the peripheral circulation.

The Relations of Liver and Pancreas.

Cammidge[44] has recently made some experiments which bear on the relations of the liver and pancreas. He estimated the amylolytic ferment in the blood—the increase in the reducing power of the blood—after hydrolysis, which he called the "difference value" and the blood sugar. *The effect of a carbohydrate meal* was observed on all these substances in patients with diseases of the pancreas and in dogs which had had varying amounts of the pancreas removed.

In patients with disease of the pancreas and in dogs in whom two-thirds or less of the pancreas had been removed there is a great increase in the "difference value" and of the amylolytic ferment of the blood of the fasting patient or dog. The carbohydrate meal causes a great fall in the "difference value," but an increase in the amylolytic ferment and in the blood sugar. This lasts for some ours and then the "difference value" rises again and the hers fall. If the whole of the pancreas is removed the ifference value" is low, but the amylolytic ferment and d sugar are higher than ever.

These experiments show that the amylolytic ferment is not secreted by the pancreas, as it was present in the greatest amount when the pancreas was completely removed. It is, therefore, suggested by Cammidge that the amylolytic ferment is formed in the liver and that its production is under the control of the pancreas. A diminution in the pancreatic function allows either an increase in the production or perhaps an escape of the amylolytic ferment into the blood. This part of the work agrees therefore with Hedon's observation on the necessity of the perfusing blood passing through the liver.

The significance of the "difference value" is much more difficult to appraise. It is present in the fasting blood in the largest amount when the pancreas is slightly damaged and in smallest amount when the pancreas is intact or absent. It decreases with the increase in the amylolytic ferment and increases with the fall of the amylolytic ferment, and is therefore in some way dependent on the activity of this ferment.

The work of Dakin and Dudley[45] on glyoxalase is also very important. They found that the liver, muscles, and blood of all animals contain a thermo-labile ferment called glyoxalase which is capable of converting methyl glyoxal into lactic acid. The pancreas, however, contained a ferment which could inhibit the action of the glyoxalase. This antiglyoxalase is water-soluble and thermo-labile, is present in pancreatic extracts and also in the pancreatic juice. The blood of muscles of diabetics, however, had less glyoxalase than usual.

If this work of Cohnheim, Clark, Dakin, and Dudley is correct the problem is an extremely complicated one. We know at present three substances which seem to play an important part. Cohnheim's substance, which is thermo-stabile, soluble in alcohol, and inhibited by trypsin, is apparently necessary for the storage of sugar in the muscles. Dakin and Dudley's substance, which is thermo-labile, water-soluble, unaffected by trypsin, is apparently necessary to prevent the conversion of the muscle sugar into lactic acid. Clark's substance, which is thermo-labile, water-soluble (and in diabetic animals must pass through the liver as well) is necessary to enable the muscles to burn the sugar. The three substances are here shown in tabular form:—

COHNHEIM'S SUBSTANCE.	DAKIN AND DUDLEY'S ANTI-GLYOXALASE.	CLARK'S SUBSTANCE.
Thermo-stabile. Soluble in alcohol. Inhibited by trypsin. Necessary for storage of sugar in muscles.	Thermo-labile. Soluble in water. Unaffected by trypsin. Necessary to prevent conversion of muscle sugar into lactic acid.	Thermo-labile. Water soluble. Necessary to enable the muscles to burn sugar.

The evidence which I shall bring forward in my next lecture from the consideration of the effect of a small dose of sugar on mild cases of diabetes suggests that the diabetic is unable to store the sugar readily, and that it circulates in the blood for a much longer period than usual. This effect may perhaps be ascribed to the absence of Cohnheim's substance in adequate amounts. (Fig. 4.) The fact that the respiratory quotient in diabetes is low shows that the body is not burning sugar, and this may be ascribed to the absence of

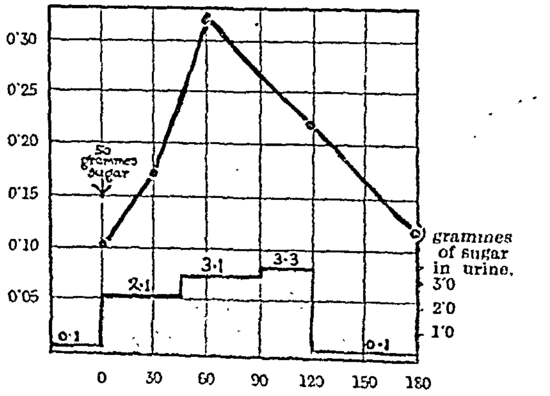

FIG. 4.—Showing the effect of 50 g. sugar on the level of the blood sugar and the sugar excreted per hour.

Clark's substance in adequate amounts. The persistence of hyperglycæmia in severe diabetes, in spite of starvation, may perhaps be due to absence of Dakin's substance.

THE MECHANISM REGULATING THE AMOUNT OF SUGAR IN THE BLOOD.

The mechanism by which the amount of sugar in the blood is regulated must next be briefly considered. The sugar in the blood seems to remain at a fairly constant amount, except when it is raised after a meal or when it is decreased after the effect of the meal has passed off. The decrease is sometimes quite marked, but after one or more hours the level of the blood sugar returns to its original level or a little lower. The mechanism by which this is achieved is a complicated one, as there are four ductless glands—the suprarenal, the thyroid, the pituitary, and the pancreas—which exert an influence on it. The suprarenal, thyroid, and pituitary all seem to belong to one group, as an increase in their activity causes a rise in the blood sugar and perhaps glycosuria. A decrease in their activities may cause an increase in the sugar tolerance. The pancreas must be placed in the opposing group, as a decrease of its functions causes a diminution of the sugar tolerance.

The methods by which these glands produce their action are still difficult to understand, but considerable information has accumulated.

The mode of action of the suprarenal gland is especially interesting. The injection of adrenalin causes an increase in the blood sugar and may therefore cause glycosuria if the level of the blood sugar rises above the leak point. Further confirmation is obtained from observations on patients as anxiety may cause a temporary glycosuria—e.g., the strain of an examination (Cannon); the anxiety of either playing or looking on at a football match (McLeod[48]). Moreover, I have found the fasting value for the blood sugar raised to 0·16 or 0·18 g. per cent. on two occasions when I have tested the sugar and tolerance of patients with diabetes innocens. On repeating the test the fasting value has always been within the normal limits. If it be accepted that adrenalin plays a part in regulating the amount of sugar in the blood the method by which the necessary amount of adrenalin is settled is not known. The adrenalin is believed to act by converting the glycogen of the liver into sugar, as most sugar is excreted when the liver contains most glycogen. But if the liver contains little glycogen the adrenalin causes an increase in the amount of glycogen in the liver. The adrenalin is excreted in the general circulation and reaches the liver by the hepatic artery as well as by the portal vein, and it is possible that it also mobilises the sugar in the muscles and brings that to the liver.

The old work of Kulz[47] bears on this point. He made some observations on the time at which the liver of rabbits contained the maximum amount of sugar. He found that 4 hours after a dose of 21 g. of glucose the liver contained very little sugar, but that it began to accumulate in the liver after 10 hours, reached its maximum after 16 hours, and was nearly all gone after the 24th hour. The adrenalin may therefore be the active agent which helps to keep the sugar content of the blood constant, but the method by which the amount of adrenalin required is determined is not yet clear. The suprarenals are under the control of the splanchnic nerves, and stimulation of these nerves causes an increase in the output of adrenalin and a rise in the blood sugar. Further, it is through the splanchnic nerves that the impulses pass from the fourth ventricle. The excretion of sugar which Claude Bernard produced by puncturing the floor of the fourth ventricle can be abolished by cutting the splanchnic nerves or by removing the suprarenal glands. At this stage the question seemed relatively simple, but later it was found that after division of all the nerves of the hepatic plexus stimulation of the splanchnic nerves did not produce any hyperglycæmia.[48] Also stimulation of the hepatic plexus could produce hyperglycæmia by itself, but not if the suprarenals had been removed.

There are therefore two factors at work: (1) presence of adrenalin; (2) an intact hepatic plexus. It seems possible that the need for the sugar reacts in some way on a centre in the brain and that the impulses pass to the suprarenals via the splanchnic nerves, and this produces more adrenalin and hence more sugar in the blood.

The evidence for the influence of the thyroid is less complete. In exophthalmic goitre the sugar tolerance may be much reduced and sugar may be excreted. The opposite is the case in myxœdema, as the sugar tolerance is much increased. Treatment with thyroid extract lowers the sugar tolerance and may cause glycosuria even in healthy people if a large enough dose be taken.

The pituitary is still less understood. Glycosuria may occur in the early stages of acromegaly, but whether this is due to a secretion from the anterior lobe or is due to pressure on the floor of the fourth ventricle is not clear. After destruction of the posterior lobe, on the other hand, the carbohydrate tolerance is much increased. Feeding with posterior lobe will reduce the sugar tolerance.

How the work of regulating the blood sugar is shared between the three glands is at present quite unknown. The pancreas is the only gland in the opposing group as far as we know. The effects of an excess of pancreatic excretion are unknown. The defects of the pancreas are, however, well known. Since the day of von Mering and Minkowski a great deal of work has been done on the effects of removal of the pancreas, notably by Starling and Allen. Allen has shown that if one-eighth to one-ninth of the whole gland is left intact the diabetes will be of a mild type, but if less than one-ninth is left the disease is of a severe type. These observations show that the pancreas supplies a secretion which is essential for the metabolism of sugar. I have already described the evidence of its mode of action.

This completes my review of the physiological aspects of diabetes mellitus. The whole subject of diabetes bristles with difficulties, as I have tried to show throughout this lecture. The more we advance our knowledge the more complicated the problem becomes, and the more there is to learn.

A SIMPLE
QUANTITATIVE SERUM-REACTION FOR THE DIAGNOSIS OF SYPHILIS
AND THE EXPRESSION OF RESULTS IN STANDARD UNITS.[1]

BY GEORGES DREYER AND HUGH KINGSLEY WARD.

(From the Department of Pathology, University of Oxford.)

QUALITATIVE AND QUANTITATIVE TESTS.

EVER since the application of the Bordet and Gengou phenomenon of complement fixation to the diagnosis of syphilis by Wassermann, Neisser, and Bruck in 1906, this reaction, generally known as the Wassermann reaction, has been our most valuable aid in the diagnosis of syphilis. During these years the technique has undergone a series of modifications with the object of enhancing the specificity and the delicacy of the reaction. The result has been that in the Wassermann reaction we now possess a practical and reliable qualitative test for the diagnosis of syphilis. If the reaction fulfils the conditions laid down by Wassermann (total absence of hæmolysis), it is for all practical purposes specific, save, perhaps, in the acute stages of malaria, in pellagra, and in yaws. On the other hand, an incomplete or negative reaction by no means excludes syphilitic infection.

The disadvantages of the method are briefly as follows:—

1. The rather complicated technique, with its many pitfalls, requires very considerable skill and experience in the handling of the various more or less unstable reagents. That this does not interfere, for all *practical purposes*, with the qualitative value of the test in the hands of highly skilled and experienced pathologists is clearly brought out by the experiments of McIntosh, Harrison, and Browning,[2] who tested 104 serums independently and arrived at nearly identical results.

2. The reaction cannot be properly standardised owing to the number of variants in it—complement and red cells varying from day to day, amboceptor and antigen varying from month to month. For this reason any attempt to determine from one time to another the titre of the serum in any given case is bound to be only approximately accurate. That this is so was clearly proved by the careful quantitative determinations of Thomsen,[3] who compared the same serums, kept under ideal conditions, at intervals of a few days. These serums did not give the same results on three different occasions.

3. Because titration is only approximately accurate and also involves very considerable labour the routine usually adopted is to use one fixed quantity of serum (0·1 c.cm) for the test, and to express the results in terms of +, ++, +++, and ++++, with a view of indicating the strength of the so-called *Wassermann substance*. The result of this procedure is that the reaction remains ++++ until near the borderline. Thus if the serum is strong the Wassermann reaction gives no indication of how the case is progressing unless and until the reaction approaches the borderline, where it may *disappear altogether*, or perhaps fluctuate between positive and negative, according to the delicacy of the reaction on the particular occasion. If the serum is weak the reaction may become negative and remain negative, or again, as before, fluctuate between positive and negative over a prolonged period.

It may be said that these fluctuations, frequently observed, are due to actual changes in the strength of the serum, but as similar fluctuations also occur when the same serum is tested on different occasions, it is, in our opinion, probable that these fluctuations are largely due to variations in the sensitiveness of the Wassermann reaction—and are not true changes in the strength of the serum. The procedure adopted by some workers of using two different amounts of complement with the fixed amount of syphilitic serum gives little or no help in this respect.

For the reasons here given the physician may receive very little guidance from the Wassermann reaction as to the result of treatment, and will often find it difficult to correlate his clinical observations with the result of the reaction.

Attempts to Dispense with the Hæmolytic System.

Owing to the complicated technique of the Wassermann reaction attempts have been made from time to time to devise a simpler reaction by doing away with the hæmolytic system. The first test of this type was the Hermann and Perutz flocculation reaction. In this the property of syphilitic serum to flocculate a suspension in saline of sodium glycocholate and cholesterin was made use of. Most observers seemed to agree that it was less delicate than the Wassermann reaction, and also gave a considerable number of false positive results. Of subsequent flocculation reactions the Sachs-Georgi is the one that has yielded diagnostic results that compare most favourably with those given by the Wassermann reaction. As a test fluid Sachs and Georgi made use of a saline suspension of a mixture of alcoholic heart extract and cholesterin. To 0·5 c.cm. of this test-fluid they added 1·0 c.cm. of serum diluted 1/10, incubated for two hours at 37° C., left the tubes at room temperature for another 20 hours, and read the results. Most observers in Germany seem to agree that this reaction gives almost as reliable results as the Wassermann reaction as carried out in Germany. On the other hand, opinions so far expressed in this country seem less favourable.

We have for years tried to standardise the Wassermann reaction and to devise a unit system for expressing its results, but in vain. An analysis of the results obtained by the flocculation test of Sachs and Georgi indicated the possibility of evolving a simple quantitative test that could be standardised. With this in view it was obvious that the use of an unstable heart extract such as that of Sachs and Georgi would defeat our aims, but fortunately Bordet and Ruelens[4] have recently shown that it is possible to prepare (for the Wassermann reaction) a heart-extract antigen that is stable and at the same time very sensitive.

To us the ideals to be aimed at in a diagnostic reaction of this kind are: (1) that the technique should be simple and accurate; (2) that it should be possible to reproduce the same experimental conditions from time to time, and that there should only be one variant —i.e., the substance to be estimated; (3) that it should be possible to determine the amount of this substance and express it in standard units per c.cm., no matter whether absolute quantities or relative proportions are made use of in the test; (4) that the standard unit should be easy to maintain and check.

TECHNIQUE.

The technique which we have evolved with these requirements in view will now be described in detail.

A. *Reagents and Apparatus Required.*

Outline.—(1) Two standardised saline suspensions of different concentrations made from a mixture of alcoholic heart extract and cholesterin; (2) serum to be tested; (3) normal saline solution for making the suspension and diluting the serum; (4) agglutination tubes, dwarf test-tubes, and stands; (5) graduated pipettes, measuring cylinder, and dropping pipette; (6) an apparatus for delivering drops of saline at a constant rate; (7) two water-baths; (8) an artificial light arrangement for reading the tubes against a dark background; (9) a six-magnification hand lens.

Detail.—1. The following solutions are necessary for making the two heart-cholesterin saline suspensions:—

(*a*) The alcoholic heart extract is prepared according to the method of Bordet and Ruelens[4]: 100·0 *g.* calf's heart muscle, freed from fat, is cut up finely, mixed with 125·0 c.cm. ordinary alcohol (94–96 per cent.) and left at room temperature in a glass-stoppered bottle for five days, shaking occasionally. The alcohol is then filtered off. The residue is dried in the incubator at 37° C. for 24 hours, 200·0 c.cm. of pure acetone is added, and the mixture kept in a glass-stoppered bottle in an incubator at 20° C. for seven days.

---

[1] Report to the Medical Research Council.

[3] Thomsen Olaf: Die quantitative Ausführung der Wassermann-Reaktion, Zeitschrift f. Immun. und Exper. Therap., 1910, 7.

[4] J. Bordet et G. Ruelens: "L'Antigène Syphilitique de l'Institut Pasteur, Bruxelles," Comptes Rendus de la Société de Biologie, T. lxxxii., Feb. 2nd, 1919.

The acetone is then filtered off, and the residue is again treated in a similar manner with 100·0 c.cm. acetone at 20° C. for one day. The acetone is again filtered off, the residue is dried in the incubator at 20° C. for two hours, and 200·0 c.cm. ordinary alcohol (94–96 per cent.) added. This mixture is put in a glass-stoppered bottle in the incubator at 20° C. for 10 days, and then filtered through filter paper. The filtrate thus prepared, limpid and golden yellow in colour, is now ready for use. It contains the acetone-insoluble alcohol-soluble substances of the heart muscle. Kept in the dark at ordinary room temperature in a tightly stoppered glass bottle, it will remain limpid and keep unchanged for a very long period.

(*b*) The alcoholic solution of cholesterin is prepared by dissolving 1·0 g. of pure cholesterin (preferably Kahlbaum's) in 100·0 c.cm. absolute alcohol. It should be kept under the same conditions as the heart extract.

(*c*) The sterile normal saline solution is prepared by dissolving 9·0 g. of pure sodium chloride in a litre of freshly distilled water and immediately sterilising in the autoclave.

The two heart cholesterin saline suspensions are prepared from these solutions (*a*, *b*, *c*) in the following manner:—

Measure 5·0 c.cm. of the heart extract (*a*) and 0·25 c.cm. of the cholesterin solution (*b*) into a clean dry tube and mix. Measure out 1·0 c.cm. of this mixture into a clean dry 100·0 c.cm. measuring cylinder, taking care that the point of the pipette is placed on the bottom of the cylinder before letting the fluid run out. Sterile normal saline (*c*) is now allowed to drop at a constant rate from a constant height directly on to the fluid at the bottom of the measuring cylinder without touching the sides of the cylinder as it drops. The saline should drop at a rate which will deliver 34·0 c.cm. in 4 min. 30 sec. The saline should drop a distance of 36·0 cm. on to the fluid.

Two suspensions of different concentrations are prepared:—

α suspension—1·0 c.cm. of the heart cholesterin mixture, into which 10·7 c.cm. of saline are dropped.

β suspension—1·0 c.cm. of the heart cholesterin mixture, into which 34·0 c.cm. of saline are dropped.

The resulting suspensions are mixed by gently inverting the cylinder. They should *not* be shaken.

α suspension is naturally more opaque than β suspension. The easiest way to measure the saline is to allow the saline to drop into the cylinder for 1 min. 25 sec. in the case of α suspension and for 4 min. 30 sec. in the case of β suspension (at the rate indicated above).

A convenient and readily made dropping apparatus for delivering the saline at this rate is described below.

Unfortunately, all attempts to make permanent standard saline suspensions that will keep indefinitely have so far met with no success, and therefore the suspensions must be freshly prepared immediately before use. Such suspensions, if made exactly according to the above directions, with the same heart extract and cholesterin, are identical from day to day in opacity, size of suspended particles, and sensitiveness, and thus permit of standardisation.

2. To obtain serums that will give reliable results it is essential that the blood should be withdrawn with due aseptic precautions and the serum kept free from infection. To carry out a full test 4–5 c.cm. of blood should be drawn. For routine purposes we have found that the most satisfactory technique to secure sterility and an ample supply of serum is as follows:—

To place the blood directly into a 6 c.cm. centrifuge tube lined with sterile saline agar (as described by A. D. Gardner[5]) and closed with a sterile indiarubber stopper. The serum is transferred by a sterile Pasteur pipette into a dry, sterile, dwarf tube plugged with cotton-wool. If the clot does not contract satisfactorily—a rare occurrence—the tube should be centrifugalised. If the syringe or needle for withdrawing the blood is kept in alcohol, the alcohol should be removed with ether and the syringe or needle dried before use, as we have found that alcohol particularly, and also ether to a less extent, is highly detrimental to this reaction, and even more so to the Wassermann reaction. The presence of even a marked amount of dissolved hæmoglobin in the serum does not interfere with the reaction so long as the serum is fairly clear. A moderate degree of turbidity of the serum, if it is not caused by infection, does not interfere with the reaction. Before testing, the serum must be heated to 53°–54° C. for 90 minutes in a water-bath.

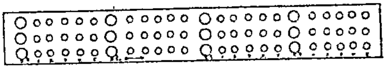
3. The sterile saline solution for dilution of serums is made up in the manner already described above.

4. The agglutination tubes[6] employed are identical with those used for the agglutination of standard cultures. The inside diameter of these tubes is 5·5–6·2 mm., the outside diameter is 6·6–7·3 mm., the length is 5·8 mm., the lower end is conical, and the upper end flanged to facilitate filling.

Dwarf test tubes measuring 7 cm. × 1 cm. should be used; all tubes should be cleaned in acid and thoroughly rinsed with distilled water to remove all traces of acid. The tubes are allowed to drain and are then dry sterilised without plugging.

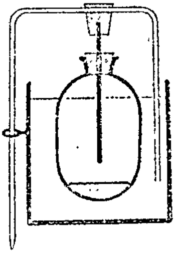
Agglutination stands. Where only a small number of serums are to be tested the agglutination stands used in the standard agglutination technique can be employed. If larger number of serums are tested it is more convenient to use a stand with three rows of holes, each row holding four holes for dwarf test tubes and 20 holes for agglutination tubes, as shown in Fig. 1.[7]

FIG. 1.



5. Two pipettes are required, a 5·0 c.cm. pipette graduated in tenths of a c.cm., and a 1·0 c.cm. pipette graduated in hundreths of a c.cm., together with a 100·0 c.cm. measuring cylinder graduated in c.cm., a dropping pipette as used in the standard agglutination technique (total length 19 cm., length of capillary portion 2·8 cm., outside diameter of the body of pipette 5·0–5·4 mm., outside diameter of capillary portion 2·36–2·41 mm., bore 0·5 mm.).

FIG. 2.



6. The simple apparatus for delivering drops of saline at a constant rate, which is here illustrated (Fig. 2), was devised for this purpose by Mr. H. F. Pierce, a co-worker in the laboratory.

The principle of the apparatus is a floating syphon. The syphon is carried on a glass bulb, counter-weighted with mercury, and floating in a cylindrical glass vessel containing the saline solution. The height of the syphon above the floating bulb is adjustable by means of a glass rod in order to be able to vary the head of fluid, and therefore the rate of dropping. The chief dimensions of the apparatus are as follows:—

Cylindrical glass vessel: height 12 cm., diameter 9 cm.

Glass float: height 10 cm., diameter 6·5 cm.

Glass syphon tube: outside diameter 6 mm., drawn out at the delivery end into a short capillary; outside diameter 2 mm.

The saline solution is poured into the cylindrical vessel, the syphon placed in position, and the flow started by suction. The height of the syphon tube determines the head of fluid and therefore the rate of delivery. Once fixed it will deliver the saline solution at a constant rate, provided the float is never allowed to touch the bottom of the cylindrical vessel. The delivery end of the syphon is held in position by a loop of wire, through which it glides as the level of the fluid falls. The apparatus, being all glass, is easy to clean.

7. Two properly regulated water-baths, one to be kept at 37° C., the other between 53° and 54° C.

---

[6] Agglutination tubes and dropping pipettes can be obtained from Messrs. Baird and Tatlock, Hatton Garden, London, E.C., or from Messrs. R. B. Turner and Co., Eagle-street, Southampton-row, London, W.C.

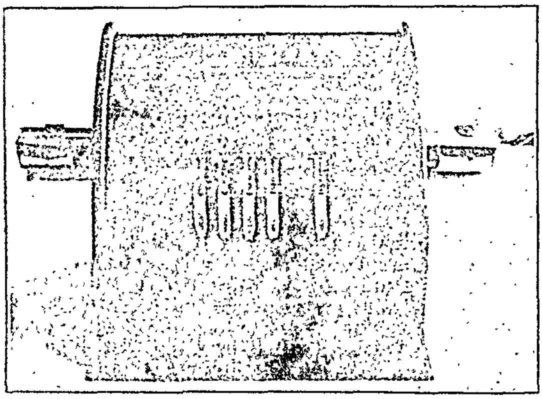
[7] These stands can be obtained from The Oxford Scientific Instrument Co., Wheatsheaf-yard, High-street, Oxford.

8. An artificial light arrangement for reading the tubes is essential.

The artificial light should be used in a darkened room. The simplest arrangement is an adjustable table-lamp fitted with an ordinary plain conical shade, covered on the outside with dull black paper. The end of the electric bulb should not project appreciably beyond the edge of the shade. For use the lamp should be tilted to such a degree that the observer does not look into the light. The tubes to be read are held against the edge of the shade, the lower end tilted towards the observer, and the meniscus of the fluid in the tube should be slightly above the edge of the shade. It is desirable to place a dull-black cardboard on the table and another resting against the further edge of the lamp-shade. A frosted bulb of 30 c.p. is used.

Where the observer has had no previous experience, and it is desirable to compare the different degrees of flocculation in the tubes to be read, an apparatus[8] for illuminating a number of tubes held in a fixed position is convenient. (Fig. 3.) It consists of a small box with a sloping front, lined inside with black velvet, and containing a long frosted electric window-light. The latter illuminates a slit in the front of the box and the tubes are placed in front of the slit. The tubes are placed in such a manner that the meniscus of the fluid is slightly above the upper edge of the slit. Again, the observer should be so placed that he cannot look into the light, which is placed just behind the upper edge of the slit.

FIG. 3.



9. A 6-magnification hand lens, which should be of reputable make and give a good depth of focus.

B. *Method of Setting Up the Test.*

Place nine of the agglutination tubes in the stand together with one dilution tube—i.e., a dwarf test tube.

TABLE I.

No. of tube.	Drops of saline solution.	Drops of serum 1-x.	Drops of suspension.	Total dilution in which serum acts.
1	0	20 1/1	6 (α suspension)	1/1·25
2	0	10 ..	15 (β suspension)	1/2·5
3	5	5 ..	15 ..	1/5·2
4	8	2 ..	15 ..	1/13·1
5	9	1 ..	15 ..	1/25·4
6	0	10 1/20	15 ..	1/46
7	5	5 ..	15 ..	1/92
8	8	2 ..	15 ..	1/232
9	9	1 ..	15 ..	1/462

It is convenient also to place the dwarf test tube containing the serum in the hole arranged for it in the stand. With the proper dropping pipette *held vertically* measure out into the nine agglutination tubes the following number of drops of saline solution, serum, and standard suspensions. (Table I.) The total dilutions given in the table are calculated by taking into account the relative volumes of the drops in the case of serum, saline, and suspension. To make up the 1/20 dilution of serum add 19 drops of saline solution to the dilution tube (when adding the saline solution to the agglutination tubes) and one drop of pure serum to the dilution tube (when adding the pure serum to the agglutination tubes). Thus a 1/20 serum dilution is obtained.

A control tube containing 20 drops of saline solution and 6 drops of α suspension, and another containing 10 drops of saline solution and 15 drops of β suspension, should always be made up and placed in the stand. It is important to note that one and the same pipette must be used throughout the whole operation.

At each stage of the procedure the pipette should be carefully washed out with distilled water and either dried out with successive quantities of acetone or dried out with successive quantities of absolute alcohol followed by successive quantities of ether. The use of an ordinary suction pump will greatly accelerate the washing and drying of the pipette. When the reagents have been added to the tubes, shake each tube thoroughly in order from right to left—i.e., beginning with the tube containing the highest serum dilution, place the stand in a water-bath at 37° C. (not in dry air) and leave it for seven hours. It is very important to arrange the level of the water in the bath so that not more than the lower half to two-thirds of the column of fluid in the tubes are immersed. Flocculation is greatly accelerated by this arrangement, and sharper readings are obtained. In the case of unknown serums, or of syphilitic serums previously found to give a weak reaction, and in the case of cerebro-spinal fluids it is sufficient to put up the first five tubes. If the limit of flocculation is not reached within the five tubes, the 1/20 dilution must be carried out. With very rare exceptions the flocculation will stop within this range of tubes. If not, a further dilution of 1/400 should be made.

Should a more precise determination of the limits of flocculation be required it can be obtained by using a stand of 12 tubes with a series of quantities given in the table contained in the Directions for Preparation and Standardisation of Agglutinable Cultures.[9] The tubes are examined after the seven hours' incubation in the water-bath at 37° C., followed by 5–10 minutes' standing at room temperature. The inconvenience caused by a seven-hour incubation can be overcome by adding the serum and saline solution to the tubes, leaving them overnight in the ice-box, adding the freshly made-up standard suspension in the morning, and incubating for seven hours.

C. *Reading of Results.*

The tubes are read in the manner already indicated under heading A. 8. The principal terms employed in describing the different degrees of flocculation met with are: total (t), standard (S), trace (tr), and nil (0).

Total flocculation (t) indicates a condition where the fluid in the tube has become nearly clear, with the bulk of the large flocculi settled down at the foot of the tube. This degree of flocculation is rarely seen.

Standard flocculation (S) is the degree of flocculation that can readily be seen with the naked eye. The fine flocculi are evenly distributed, of uniform size, and definitely separated from one another. The fluid accordingly shows some degree of clarification.

Trace (tr) is the term applied to a very fine flocculation, not visible with certainty to the naked eye by most persons, while readily visible with the 6-magnification lens.

Nil (0) indicates that no flocculation is recognisable by means of the 6-magnification lens, and should therefore be identical with the control tube.

Naturally, there are degrees of flocculation which fall in between total, standard, trace, and nil. For these the following terms are used: *Total minus* (t–), where there is marked clarification of the fluid; the flocculi are large, well separated, and some have settled down at the foot of the tubes. This degree of flocculation is as common as total flocculation is rare. On each side of standard flocculation we find *standard plus* (s+) and *standard minus* (s–). In the former the flocculi are larger than those seen in standard flocculation; they are uniformly distributed, and clarification is more marked: in the latter is seen a finer flocculation than standard and a correspondingly less marked clarification. Similarly, we recognise a *trace plus* (tr +) and a *trace minus* (tr –), the former representing something more than trace but less than standard minus (s −), being on the limit of naked-eye visibility for most persons, while, of course, easily detected with the 6-magnification lens. The latter, trace minus (tr −), is a very fine degree of flocculation that can only be detected by means of the 6-magnification lens. Finally, on occasions it may be difficult, even by means of the 6-magnification lens, to decide with certainty whether flocculation is definitely absent, the term *query trace* (tr ?) is then applied. Any tube showing less than trace should for safety be compared with the control tube showing no flocculation.

---

[8] The apparatus can be obtained from the Oxford Scientific Instrument Co., Wheatsheaf Yard, High-street, Oxford.

[9] Issued on behalf of the Medical Research Council by the Standards Laboratory, Department of Pathology, University of Oxford.

To secure uniformity in readings by various observers tubes exhibiting two degrees of flocculation—viz., standard and trace—and a control tube without flocculation have been prepared and made permanent by means of formalised gelatin. A permanent tube exhibiting total or total minus flocculation is not necessary, as this reading is obvious from the description.

D. *Expression of Results in Standard Units.*

All readings should be expressed in terms of standard flocculation units. The number of standard flocculation units in a serum is arrived at in the following manner:—

The amount of serum which, when made up to 1·0 c.cm. volume with normal saline solution, causes standard flocculation on being mixed with 1·5 c.cm. of a particular β suspension and maintained at 37° C. at seven hours, is assumed to contain four (4) units.[10] On this basis the strength of a serum—whether measured by absolute quantities or relative quantities as indicated here—can be expressed in terms of standard units per c.cm. All that is *required is to multiply the dilution in which standard* flocculation occurs by a factor representing the sensitiveness of the particular suspension used. This factor will hereafter be called the "suspension factor."

Example.—If a serum acting in a total dilution of 1/46 (tube 6) causes standard flocculation, then 46 (total dilution) × 1·6 (suspension factor) = 73·6 units. Therefore this particular serum contains 73·6 units per c.cm. For these standard units we propose to adopt the term Σ *units* (Sigma units), and shall refer to them in future as such.

As heart extracts prepared at different times and places may vary, it is essential to compare the relative sensitiveness of their suspensions with the original one, as otherwise a uniform standard for different workers could not be maintained. It is obvious that the more sensitive a particular suspension is the smaller will its suspension factor become, and vice versa. When such a comparison is carried out a long series of tubes, with a very gradual increase of dilution, should be used, as in the case of the standardisation of agglutinable cultures. Owing to the great increase in dilution of the syphilitic serum in successive tubes, it will commonly happen that no tube in the series exhibits standard flocculation. Nevertheless, results of sufficient accuracy for ordinary purposes can be calculated by means of an interpolation table (Table II.) constructed for this purpose.

TABLE II.

t− = 2·00
s+ = 1·35
S = 1·00
s− = 0·86
tr+ = 0·68
tr = 0·58
tr− = 0·50
tr? = 0·37
0 = 0·25

The readings from s + to tr are in general the readings giving the most accurate results. The table is used as follows:—

Supposing no tube in the series shows S flocculation, and tube 6 shows s + flocculation and tube 7 tr + flocculation, then the number of units in tube 6 = 46 (total dilution) × 1·35 (interpolation figure) × 1·6 (suspension factor) = 99·4 Σ units, and the number of units in tube 7 = 92 (total dilution) × 0·68 (interpolation figure) × 1·6 (suspension factor) = 100 Σ units. The average is 99·75 Σ units, or 1·0 c.cm. of the serum contains *practically 100 Σ units.*

On the other hand, one may find quite considerable discrepancies between two readings, as in the following case, where tube 3 gives s − and tube 4 tr − flocculation. The number of units in tube 3 = 5·2 (total dilution) × 0·86 (interpolation figure) × 1·6 (suspension factor) = 7·2 Σ units, while the number of units in tube 4 = 13·1 (total dilution) × 0·5 (interpolation figure) × 1·6 (suspension factor) = 10·4 Σ units. The average is 8·8 Σ units, or 1·0 c.cm. of the serum contains approximately 9 Σ units.

The subsequent table, Table III. (total dilution × interpolation figure), is computed with the aim of minimising the labour in calculating the unit-content per c.cm. It must be clearly understood that the figure given in this table must always be multiplied by the suspension factor for the given heart extract to arrive at the number of standard units.

TABLE III.

Degree of flocculation	Number of tube.								
	1	2	3	4	5	6	7	8	9
t−	2·5	5·0	10·4	26·2	52·8	92·0	184·0	464·0	924·0
s+	1·7	3·4	7·0	17·7	35·7	62·0	124·0	313·0	623·0
S	1·25	2·5	5·2	13·1	26·4	46·0	92·0	232·0	462·0
s−	1·1	2·1	4·5	11·3	21·8	40·0	79·0	200·0	398·0
tr+	0·9	1·7	3·5	8·9	18·0	31·0	63·0	158·0	314·0
tr	0·75	1·4	3·0	7·6	15·3	27·0	53·0	135·0	268·0
tr−	0·6	1·2	2·6	6·5	13·2	23·0	46·0	116·0	231·0
tr?	0·4	0·9	1·9	4·8	9·8	17·0	34·0	86·0	171·0
	—	0·6	1·3	3·3	6·6	12·0	23·0	58·0	115·0

In the calculation of the unit-content of a given serum it must be borne in mind that *inhibition zones* are a very frequent occurrence in this reaction. By inhibition zones we mean the phenomenon, exhibited by certain serums, of showing in high concentrations a *distinctly weaker flocculation* than when more dilute. This phenomenon is in no way peculiar to this reaction, but is frequently encountered in other serum reactions—viz., agglutination, bacteriolysis, hæmolysis. The inhibition zone frequently extends from tube 1 (total *dilution 1/1·25) as far* as tube 5 (total dilution 1/26·4), but not often further than that. It is on the whole most marked in cases of secondary syphilis, though occasionally present in other serums showing a high titre. In weak serums, fortunately, it is in general much less pronounced, *thus not interfering* with the diagnostic value of the reaction. The treatment of the serum before testing has a very marked influence on this phenomenon. An unheated serum or a serum heated to 53°–54° C. for a short time (5–10 minutes) will usually show a much more *pronounced zone* of inhibition than the same serum heated to 53°–54° C. for 60–90 minutes. In fact, if the serum is unheated or heated for only a short time the reaction may be almost entirely masked by the inhibition, while the same serum properly heated will give a sharp and clear reaction. For the above reasons it is essential to examine at least the first five tubes before pronouncing a serum negative.

In using Table III. for calculating the unit strength of a serum the inhibition zone should be entirely ignored and the unit calculated *only from* those tubes showing a definite fall in degree of flocculation with progressive dilution of the serum, as otherwise the strength of the serum would be underestimated. To illustrate this a serum recently tested gave the following readings: tube 1 (1/1·25), tr?; tube 2 (1/2·5), tr?; tube 3 (1/5·2), tr?; tube 4 (1/13·1), tr +; tube 5 (1/26·4), S; tube 6 (1/46), tr −; tube 7 (1/92), 0. This serum contains 40 Σ units per c.cm.

E. *Certain Precautions to be Observed.*

1. If a serum obviously infected gives a negative reaction the reaction may be accepted as valid, as in our experience we have never found a positive serum which has become infected give a negative reaction. On the other hand, all positive reactions in infected serums must be discarded and new specimens examined. For we have found that a positive serum may show twice the number of units as the result of infection, and occasionally a negative serum may give a positive reaction.

2. No preservatives, such as phenol, formalin, &c., should be added to any of the reagents, as experiments have shown that they either interfere with the re

or cause false positive reactions.

3. All tubes must be scrupulously cleaned

tilled water after soaking in acid in order to fr from all traces of the latter, as acid produces a flocculation in the serum-suspension mixture.

---

[10] It is to avoid the expression of positive results in fractions of a single unit that four units are taken instead of one unit as the basis of this unit system.

4. The temptation to increase the delicacy of the reaction by incubating for 18–24 hours must be resisted. This prolonged incubation encourages bacterial growth, which in many cases causes false flocculation. This prolonged incubation, as a matter of fact, does not make the reaction more delicate than incubation for seven hours in a water-bath, where the water-level is properly adjusted (see under heading B).

F. *Interpretation of Results.*

1. *Cases with no definite history of syphilis.*—Serums containing less than one unit are considered to give a negative reaction. Serums containing four or more units are considered to give a positive reaction. Serums containing from one to four units should not be definitely accepted as positive until the test is repeated and confirmed, owing to the fact that infection of the serum may have been overlooked at the time of setting up the test. False positive results are very rare, but the responsibility of declaring a non-syphilitic case to be positive is so great that we have adopted this precaution to minimise the danger of making such a mistake, without at the same time lowering the diagnostic value of a weak reaction. Further experience may lead to the raising or lowering of these limits.

2. *Cases with a definite history of syphilis.*—Serums containing less than one unit are considered to give a negative reaction. Serums containing more than one unit are considered to give a positive reaction.

3. *Cerebro-spinal fluids.*—These fluids, if containing less than one unit, are considered to give a negative reaction. Cerebro-spinal fluids containing more than one unit are considered to give a positive reaction. Infection in cerebro-spinal fluids is so rare, and so easily seen when present, that the danger of making a mistake does not exist.

In general we have found that untreated cases in the secondary stage, untreated tertiary cases with gummata, and untreated cases of congenital syphilis show a high unit-content in the serum—i.e., from 50 up to even a 1000 or more Σ units. While, on the other hand, untreated early primary cases, or treated late primary, secondary, and tertiary cases show a low unit-content in the serum, or are negative. Cerebro-spinal fluids show a comparatively low unit-content as compared with serums.

RESULTS.

By the method described above in detail we have examined 1077 serums and cerebro-spinal fluids from definite cases of syphilis, from cases of suspected syphilis, and from patients suffering from various other diseases, including a large number of cases of tuberculosis with tubercle bacilli present in the sputum, as well as a number of known healthy normal persons. The results are tabulated in Table IV. All the serums and cerebro-spinal fluids referred to have been tested by the Wassermann reaction either by ourselves or in the pathological departments of Sheffield University, Guy's Hospital, King's College Hospital, Brompton Hospital, and the Radcliffe Infirmary, Oxford, by means of one or other of the accepted methods described in the special report on the Wassermann reaction issued by the Medical Research Council.

As one of our aims has been to compare the results obtained by the reaction here described with those of the Wassermann reaction, the table has been arranged with this object. In order to secure as clean-cut a comparison as possible we have eliminated doubtful reactions in the Wassermann reaction by calling ++++, +++, ++ positive, and +, ±, and − negative. In our own reaction, which we propose to call the Σ reaction (Sigma reaction), we have drawn the line between positive and negative reactions as described under heading F. To secure unbiased results it is important, as in all tests of this kind, that the observer should be ignorant of the origin of the serum. Therefore all readings have been made by one of us, observing these conditions.

From Table IV. it is seen that out of the 1077 cases 63·6 per cent. gave a negative reaction by both methods; out of 386 cases with definite evidence of syphilis the Wassermann reaction gave a positive result in 327 cases, while the Σ reaction gave a positive result in 381 cases. Thus the Σ reaction gave positive results in 18 per cent. more cases than the Wassermann reaction in this series of tests. It only failed in 5 cases to reveal the presence of syphilis, while the Wassermann reaction failed in 59 cases. In 5 cases with no history or definite evidence of syphilis the Wassermann gave a ++ reaction in 4 cases, and the Σ reaction gave a reading of 2·4 Σ units in one case (negative Σ reaction on repetition). Among the cases examined were 58 cases of tuberculosis with tubercle bacilli present in the sputum. Of these 52 gave a negative Σ reaction and also a negative Wassermann reaction, while 6 gave a positive Σ reaction, and also a ++++ Wassermann reaction. Two cases of scarlet fever were negative by both methods. Eighty-two cerebro-spinal fluids were examined.

TABLE IV.

No. of cases.	History of Cases.	Wa. R.	Σ R.
686	These include normal cases, cases suffering from other diseases, treated cases of syphilis which no longer give a positive reaction, and one case of very early primary syphilis.	−	−
322	These include cases where there was a definite history or clinical evidence of syphilis, and a few where the diagnosis was based on a ++++ Wassermann reaction.	+	+
59	Cases where there was a definite history or clinical evidence of syphilis.	−	+
5		+	−
4	Cases where there was no definite history or clinical evidence of syphilis.	+	−
1		−	+

It has been our experience that in the case of cerebro-spinal fluids the Wassermann reaction is as delicate as the Σ reaction. This, no doubt, because more cerebro-spinal fluid than serum is employed in the Wassermann reaction. In the case of serum, however, the Wassermann reaction has proved less sensitive. This is readily explained by the fact that relatively larger quantities of serum can be used in the Σ reaction without danger of obtaining false positive reactions. Accordingly, a treated case of syphilis will sometimes continue to give a positive Σ reaction after the Wassermann reaction has become negative. But, of course, a negative Σ reaction does not necessarily indicate cure.

Up to the present moment we have not had many opportunities of following the Σ unit-content in the serum of cases under treatment, but the following table (Table V.) will illustrate some of these. These cases all show a gradual decrease in their Σ unit-content during treatment, corresponding with improvement clinically. It would, however, be premature to generalise from only a few cases as to a definite correlation between clinical improvement and fall in Σ units. Only observations on a great number of cases can settle this point.

TABLE V.

Case 1.		Case 2.		Case 3.*		Case 4.	
Date.	Sigma unit.	Date.	Sigma unit.	Date.	Sigma unit.	Date.	Sigma unit.
8/12/20	5·4	1/2/21	117·0	23/12/20	9·4	4/12/20	269·0
16/12/20	4·3	12/2/21	48·0	28/12/20	3·8	7/12/20	242·0
23/12/20	3·2	19/2/21	40·0	19/1/21	4·0	21/1/21	61·0
31/12/20	2·2	4/3/21	24·0	23/1/21	3·0	21/2/21	19·2
8/1/21	2·9						
23/1/21	1·4						

With the exception of Case 1, these gave ++++ Wassermann reactions throughout.

* Cerebro-spinal fluid.

Where in the same case the result of the Wassermann reaction has fluctuated between positive and negative, such fluctuations have so far not been observed in the case of the Σ reaction.

Remarks on the Flocculation Reaction of Sachs and Georgi and Subsequent Workers.

In our opinion the reasons why the Sachs-Georgi reaction, with its subsequent modifications, has not come into general favour in this and other countries are:—

1. The fixed quantity of serum—viz., 0·1 c.cm. acting in a total dilution of 1/15—does not give the maximum number of positive reactions, because the quantity of serum used is insufficient. If the quantity of serum is increased to overcome this disadvantage a certain number of strong serums will give a negative reaction, owing to the inhibition zone phenomenon. Obviously the logical method of improving the technique should have been to set up a series of tubes with falling quantities of serum and constant quantities of suspension, though this procedure seems not to have been adopted.

2. In order to enhance the delicacy of the reaction Sachs and other workers increased the time of incubation from 2 hours at 37° C. to 18-24 hours at 37° C. This modification certainly increased the delicacy of the reaction, but unfortunately gave a certain number of false positive reactions. These were, in our opinion, almost certainly due to bacterial growth encouraged by prolonged incubation, and leading to false flocculation.

3. The technique does not lend itself to standardisation because (a) the heart extract is unstable, and (b) the method of making the suspension from the heart extract is not automatic, and so the suspension will vary, as regards opacity and size of suspended particles, with different workers.

Some Theoretical Aspects of the Σ Reaction.

Having found that the Wassermann reaction and the Σ reaction gave, in most cases, closely identical diagnostic results, it became of interest to try to ascertain whether the active substance in both was the same or different. It is well known that a syphilitic serum before heating usually gives a much stronger Wassermann reaction than the same serum after heating to 56° C., and that the longer the serum is heated the less active it becomes. It was therefore important to ascertain whether heating produced the same weakening of syphilitic serum when tested by the Σ reaction. A strong syphilitic serum unheated, and heated at 54° C. for 5 min., 10 min., 20 min., 30 min., 60 min., 120 min., 240 min., was tested quantitatively by both reactions. In the Wassermann reaction the active substance apparently lost half its strength when heated for 30 min., and three-quarters of its strength when heated for 240 min., whereas heating produced no change in the strength of the active substance as measured by the Σ reaction save in the higher concentrations, where the inhibition zone was definitely diminished by the more prolonged heating.

The following seems to us a simple interpretation of the connexion between these divergent results:—

1. That in the case of the Wassermann reaction two substances act simultaneously, the one a thermostable substance ("x" substance) present only in syphilitic serums and the other a thermolabile substance ("y" substance) present in normal serums to a greater or lesser degree.

2. That also in the case of the Σ reaction these two substances take part in the reaction, the "x" substance causing the flocculation and the "y" substance causing the inhibition zone in the higher concentrations, but not influencing the end-titre of the serum.

3. That as the Wassermann reaction is in reality a negative reaction (i.e., prevention or reduction of hæmolysis) it is natural that an inhibitory substance in the serum should enhance the reaction by aiding in the inhibition of hæmolysis. It is then easy to see why, when a syphilitic serum is heated and the thermolabile inhibitory "y" substance is weakened, the Wassermann reaction is reduced in strength, while the Σ reaction, being a positive reaction and depending on the thermostable "x" substance alone, is not reduced in strength by heating. This explanation is also in agreement with the observation that the serums from persons suffering from certain diseases other than syphilis may give a positive Wassermann reaction when unheated ("y" substance present), but a negative reaction after heating ("y" substance reduced or destroyed).

A further support to this view was obtained by the examination of four serums supplied by Dr. W. d'Este Emery. We tested these serums, and found them all to contain 6·4 Σ units. Subsequently we learned from Dr. Emery that he had divided one serum into four parts, and heated the first part at 55° C. for 10 min., the second for 20 min., the third for 30 min., and the fourth for 40 min. He had then tested them quantitatively by the Wassermann reaction, and found their respective strengths to be 14·6, 8·1, 8, and 4·2 of his units.[11]

In testing a large number of syphilitic serums we have found a certain number of cases where the Wassermann reaction was strongly positive, while the Σ reaction gave comparatively few units, and on the other hand, cases where the Wassermann reaction was only weakly positive or negative, and the Σ reaction gave a comparatively large number of units. This discrepancy in results is, in our opinion, due to the varying amount of "y" substance in different syphilitic serums. A still further support of this contention is that most of the serums that give a positive Σ reaction and a negative Wassermann reaction show no inhibition zone in the Σ reaction.

Conclusions.

1. The reaction for the diagnosis of syphilis described here has yielded in our hands diagnostic results that compare more than favourably with the Wassermann reaction as carried out in this country.

2. The results obtained are quantitative as well as qualitative.

3. The reaction can be standardised, and the results can therefore be expressed in standard units, thus allowing direct comparison of the results obtained by various workers.

4. It is, therefore, possible to follow accurately the changes in the unit-content of the serum in a case of syphilis under treatment, and in this way to ascertain whether clinical improvement is regularly accompanied by a fall and an exacerbation by a rise in the unit-content of the serum.

5. This important point once settled, it will be possible to compare accurately the relative merits of different methods of treatment.

Our best thanks are due to Professor J. S. C. Douglas, Sheffield University; to Dr. E. F. Skinner, Royal Hospital, Sheffield; to Mr. D. Green, Royal Infirmary, Sheffield; to Mr. W. W. King, Jessop Hospital for Women, Sheffield; to Dr. C. P. Symonds and Dr. R. Hearn, Guy's Hospital; to Dr. W. d'Este Emery, King's College Hospital; to Dr. A. C. Inman, Brompton Hospital; to Dr. T. E. Osmond and Dr. H. K. Hamilton, St. Thomas's Hospital; and to Dr. A. G. Gibson, Radcliffe Infirmary, Oxford, all of whom have helped us with material, clinical and pathological reports. Our special thanks are due to Miss Jörgenson, Dr. F. G. Hobson, and to Dr. P. H. Jones, all of the Department of Pathology, University of Oxford, for the great assistance they have rendered us in this work.

---

[11] Incidentally we may mention that these serums had been kept for two years in glass phials at room temperature. Dr. Emery carried out the quantitative Wassermann reaction, referred to above, two years ago.

BRITISH SPA FEDERATION.—A notice has been issued on behalf of the Federation—comprising the Spas of Bath, Buxton, Cheltenham, Droitwich, Harrogate, Llandrindod Wells, Leamington, Woodhall, and New Zealand—which emphatically contradicts all statements giving the impression that these spas are closing on account of lack of fuel. There is no truth in such statements; the fuel-supply arrangements at all the spas named are such as to enable them to carry on for some time to come. The opposite impression is widespread, as proved by the numerous letters and telegrams now arriving at the spas, but there is no fear of any such disastrous position.

A REPORT ON THE FIRST YEAR'S WORK OF A CLINIC FOR SYPHILITIC CHILDREN.*

BY REGINALD C. JEWESBURY, M.A., M.D. OXON., F.R.C.P. LOND.,

PHYSICIAN IN CHARGE OF THE CHILDREN'S DEPARTMENT AT ST. THOMAS'S HOSPITAL, LONDON.

RATHER more than a year ago it was decided to form a special clinic in the Children's Department of St. Thomas's Hospital for children suffering from syphilitic infection. One morning a week has been set aside for this clinic, which draws its cases from the rest of the children's department and other special departments, including that for venereal disease, under the direction of Colonel L. W. Harrison, D.S.O.

I wish to confine my remarks to the findings of this clinic. During the first 12 months a total of 145 children were seen whose mothers were known to be syphilitic. Of these, 9 mothers became infected after the births of their children, hence the disease in these children was acquired. Of the remaining 136 mothers, infected *before* the birth of the child, 47 had treatment before or during pregnancy. In 89 cases the mothers had received no treatment previous to the birth of the child.

Incidence.

First with regard to the incidence of the disease in families as it affects the children born of syphilitic parents; in about 50 per cent. of the cases the disease was most marked in the earlier pregnancies, and appeared to become gradually attenuated, apparently healthy children coming at the end of the family (Regular type). But in just as many cases children apparently free from infection cropped up irregularly in the midst of definitely syphilitic children and miscarriages (Irregular type).

Examples of Regular Type of Family.

A. (i.)

1, 2, 3. Healthy children.
Infection—
4, 5. Premature child, lived one day.
6. „ „ stillborn.
7, 8. Stillborn. 9. Miscarriage.
10, 11. Apparently healthy children. W.R. negative.

A. (ii.)

1. Died at 18 months. "Fits."
2. Miscarriage at 4½ months.
3, 4. „ „ 6 weeks.
5. } Twins. { D, syphilitic child; Wassermann positive.
6. } Twins. { M, apparently healthy; „ negative.

In this case the syphilitic twin showed obvious clinical signs of disease, whilst the other one was free from all such signs, and the Wassermann reaction was repeatedly negative up to 6 years of age.

Examples of the Irregular Type of Family.

B. (i.)

1. Seven-months' child; died at 3 days.
2. Eight „ „ „ 7 „
3, 4. Stillborn.
5. Now living, aged 19 years; healthy.
6. „ „ „ 17 „ „
7. Stillborn. 8. Died at 7 days.
9. Stillborn; macerated fœtus. 10, 11. Miscarriage.
12. Now living, aged 9 years; W.R. +; interstitial keratitis.
13, 14. Miscarriage. 15. Twins, stillborn. 16. Miscarriage.

B. (ii.)

1. Died at 9 months.
Then six miscarriages.
8. Died at 3½ years ("heart disease").
9. Now living; W.R. +++.
10. Died at 2 years.
11. „ „ 11 weeks ("bronchitis").
12. „ „ 2½ years ("wasting").
13. Now living, aged 4 years; apparently healthy; W.R. negative.
14. Died at 14 months (blind).
15. Now living, aged 1 year; W.R. +++.
Mother, W.R. ++++.
Treatment begun since birth of last child.

Signs in the Child.

(1) A few children of syphilitic mothers who had received no treatment were quite free from any signs, and have given negative Wassermann reactions even up to the age of 10 to 14 years.

(2) Many children showed the usual signs seen in typical congenital syphilis, in whom rash and snuffles appeared two to eight weeks after birth.

(3) In a certain number of children seen, in whom there was no history of previous symptoms, symptoms developed late, after the fifth or sixth year—i.e., "lues tarda." This group amounted to 10 per cent. of all cases examined.

In these children lesions of the following structures were present: bones—periostitis; joints—synovitis; eyes—interstitial keratitis; brain—particularly affecting mental condition; ears—deafness; and teeth.

Cases Illustrative of Late Changes.

CASE 1.—E. F., boy, aged 12 years. Family history: two stillborn children previous to birth of this child. The latter healthy at birth; full time; no rash or snuffles; apparently normal child up to 5 years. First changes were mental, lack of concentration, loss of memory, &c. Boy much undersized; no definite physical stigmata. Skin, teeth, and bones—no signs. Eyes: pupils sluggish to light, equal. No keratitis; fundi *normal*. Viscera: spleen and liver not enlarged; reflexes normal; no ataxy. W.R. of blood and cerebro-spinal fluid ++.

CASE 2.—J. R., boy, aged 11½ years. Family history as follows: (1) Died soon after birth; (2) stillborn; (3) died at birth; (4) stillborn; (5) the patient, W.R. ++++; (6) living, W.R. +++; (7) living, W.R. +++; (8) living, W.R. –. No definite notes of mother's treatment; said to have had some treatment five years before birth of this child. Child full time, no signs during infancy. "Meningitis" at 2 years, very ill for two months, good recovery, well up to 9 years, then complained of frequent headaches, became dull and stupid. At 10 years became clumsy and began to lose use of limbs. Sight good. Not deaf. A big, well-developed boy, coarse features, high palate, very dull. Slight glandular enlargement. No other signs. Fundi *normal*. *Reflexes normal*. W.R. *reduced* after seven injections N.A.B. and mercury by mouth.

Wassermann Reaction as a Means of Diagnosis.

This has been found to be a very valuable and reliable test. In the case of syphilitic infants, the reaction is often negative during the first few months of life and later becomes positive. In cases where the test is negative at first it has been repeated every six months until the child is 2 years old. The reactions have been carried out in the Pathological Department under the direction of Professor L. S. Dudgeon.

Effect on Child in Untreated Syphilitic Mother.

Seventy-seven families investigated; total number of pregnancies, 322. Of these 97 (30·2 per cent.) resulted in miscarriage or stillbirth, 73 (22·8 per cent.) resulted in death in infancy or early childhood, and 152 (47·0 per cent.) were still alive at time of investigation. Mortality of children born alive = 32·4 per cent.

Effect on Child when the Mother was Treated Before or During Pregnancy.

Number of cases investigated, 43. Treatment varied from three courses of N.A.B. and mercury down to a few doses of mercury as late as the ninth month of pregnancy. Number of cases treated effectively before or during the early stages of pregnancy, 39. Total number of pregnancies, 53. Of these, 1 resulted in miscarriage, 6 in death in infancy, 46 in living children. There were therefore 87 per cent. of living children at time of examination. Actual mortality of this series of children was 11·5 against 32·4 of the former series. It was found that where the treatment of the mother was not begun until the seventh month or later of pregnancy that the child usually showed well-marked evidence of syphilis, but in the majority of mothers who had received treatment not later than the fifth month of pregnancy the children were born apparently healthy and gave negative Wassermann reactions.

CASE 1.—Mother treated two N.A.B. injections at eighth month and Hg by mouth. Child showed syphilitic lesions at 3 months.

CASE 2.—Mother treated six N.A.B. injections at seventh and eighth months and Hg by mouth. Child syphilitic and W.R. + – at 4 months.

---

* A summary of this work formed a contribution to the recent discussion on congenital syphilis held by the Children's Section of the Royal Society of Medicine.

CASE 3.—Mother treated sixth, seventh, and eighth month with seven N.A.B. injections and Hg injections. Child healthy and W.R. negative up to 10 months.

CASE 4.—Mother, who had had four miscarriages and four children dying early in infancy with strongly positive W.R., was treated fourth to eighth month with five N.A.B. injections and Hg by mouth. Child born healthy; under observation for one year and nine months, remaining healthy, and W.R. negative.

Effect of Treatment on the Child.

Method.—In most cases novarsenobillon was given intramuscularly into the buttock. Dose 0·015 g. per kilo of body weight, with gradually increasing doses, at intervals of one week, for six injections. In some cases a second course has been given at an interval of about three months. Simultaneously, mercury in the form of hydrarg. cum cret. in ½–1 gr. doses by the mouth t.d.s., this being kept up regularly. In a few severe cases mercurial inunction has been ordered. In the majority of cases the N.A.B. injections have caused no kind of ill-result. A few cases were followed by pain for some time after, and induration at the site of injection. No case has been followed by suppuration. In a few cases a slight general reaction was set up, with headache, drowsiness, and vomiting, usually not lasting longer than 12 hours. In the older children the N.A.B. has been given intravenously.

Taking blood from child for Wassermann reactions.—(1) From vein of scalp or arm or internal jugular vein depending on age; (2) from heel into capillary tube; (3) from longitudinal sinus through anterior fontanelle. (This method only in a few cases.)

Effect of Treatment on Wassermann Reaction in the Child.

In 30 cases receiving full course of N.A.B. and Hg and kept under observation the W.R. has been changed from "positive" to "negative." In some a strongly positive reaction has been reduced. In some the reaction has not been affected after a course of six injections of N.A.B. and Hg. The cases benefiting least by treatment with regard to the Wassermann reaction and physical signs are those of the late manifestations affecting children from 5 to 10 years, and especially those cases in whom the central nervous system is involved.

Effect of Treatment on Clinical Signs of Disease in the Child.

Early signs quickly cleared up, especially rashes and condylomata. Rhinitis less easily cured. Usually rapid improvement in general condition, with steady gain in weight. Liver and spleen reduced in size.

Late cases.—No case of disease of the central nervous system affected. Interstitial keratitis; some definite improvement of vision in several cases. Periostitis definitely improved.

The number of cases is rather small so far, but I hope this analysis of them will be considered worthy of recording. I am indebted to several kind assistants in this work, but particularly to Dr. J. C. Spence, who has kept very careful notes of every case seen and has also helped with the clinical work.

SIMILARITY OF EFFECTS PRODUCED BY ABSENCE OF VITAMINS

AND BY EXPOSURE TO X RAYS AND RADIUM.

BY W. CRAMER, D.Sc. EDIN., PH.D. BERL., M.R.C.S.,
A. H. DREW, D.Sc. LOND.,
AND
J. C. MOTTRAM, M.B. LOND., D.P.H.
(From the Imperial Cancer Research Fund, and from the Radium Institute, London.)

FROM the fact that the absence of vitamins from the diet leads to a gradual decline of the higher animals, and if sufficiently continued is incompatible with maintenance of life in these animals, the important generalisation has been drawn that vitamins are essential for the life of the cell. Histological investigations of the tissues and organs of animals kept on such a diet have so far failed to reveal any lesion sufficiently gross and affecting a vital organ which would account for the decline or the death of the animals. Our own observations on mice and rats kept on a diet completely free from vitamins have, with the one exception presently to be mentioned, given the same result. Even the finer cytoplasmic structure, as expressed in the condition of the mitochrondria, is not altered deeply enough to account for the condition of decline and the death of the animals. Nor does the general condition produced by the absence of vitamins help to an understanding of the manner in which they act. For the general condition of these animals is simply one of inanition, and many of the changes described as occurring in the tissues of animals kept on a vitamin-free diet are similar to, or identical with, those produced by chronic starvation. The hypertrophy of the adrenals may be quoted as an example.[1,3]

It appears to us that this hypertrophy of the adrenals in the absence of vitamins is an argument against the generalisation that vitamins are essential to the life of every cell. They do not appear to be essential to the life of either the cortical or the medullary cells of the gland. Subsidiary assumption would have to be made, for instance, that this organ is distinguished by a large store of vitamins. But such an assumption is negatived by the experimental test,[3] at least as regards the fat-soluble vitamin, and has never been demonstrated for the water-soluble vitamin. In mice and rats kept on a vitamin-free diet very active growth changes, as evidenced by the occurrence of mitoses, have also been observed in the cells of Lieberkühn's follicles, even in the last stages of avitaminosis. Similarly transplanted tumours show active growth in animals kept on a vitamin-free diet and suffering severely as the result of the absence of vitamins.

Vitamins Unnecessary for Life of Individual Cells.

The generalisation that vitamins are necessary for the life of the cell has been extended so as to cover even the lower forms of life, plants, bacteria, yeast cells, &c. The recent work of Lumière[4] has shown that so far as these lower forms of life are concerned this view was based on faulty experimental observations. It is therefore important to realise that what has been experimentally established is the fact that vitamins are essential for the maintenance of life of a highly differentiated animal as a whole, *but not necessarily, or probably, of its individual cells.*

There is, however, one tissue which is specifically and profoundly affected by the absence of vitamins from the diet—namely, the lymphoid tissue. In mice and rats kept on a diet completely free from vitamins there is a great atrophy of the lymphoid tissue, which is obvious even to the naked eye. The spleen is shrunk to a narrow ribbon; the thymus, which even in adult rats and mice remains relatively a large organ filling the upper part of the thorax and covering the base of the heart, becomes so small as to be hardly visible. The Peyer's patches, which are prominent in normal animals, are difficult to identify with the naked eye. Microscopically these organs, especially the spleen, are found to contain very few leucocytes. The ordinary lymph glands may not be macroscopically smaller than normal, but under the microscope are found to be almost bare of lymphocytes. They consist almost entirely of endothelial cells and large empty lymph spaces. The blood picture, as shown by a differential count, shows a reduction in the number of lymphocytes and an increase in the number of polymorphonuclear leucocytes.

Extreme Reduction of Number of Lymphocytes.

As an example of the degree to which the lymphocytes may be affected, the following extreme figures obtained in a mouse and a rat in the final stages of avitam may be given. These animals did not suffer from intercurrent infection. The differential counts figures varying a good deal for different indiv animals, and the examples given represent the ext-

—	Lymphocytes.	Large mononuclears.	Polymorphs.	Mast cells.	Eosinophiles.
	Per cent	Per cent.	Per cent	Per cent.	Per cent.
Avitamin rat No. 130	25	15	57	2	1
Normal rat.	54	7	37·5	1·3	0·2
Avitamin mouse No. 140.	6	23	71	0	0
Normal mouse.	60	21·5	17	1·4	0·1

change so far as the lymphocytes are concerned. The figures for the normal animals are taken from Eyre's Bacteriological Technique (second edition, p. 374), and represent the average of a large number of counts. Our own observations on normal animals agree with these figures within narrow limits.

Similarity with Action of X Rays and Radium.

This condition of the lymphoid tissue is practically identical with that produced by exposure to X rays and radium. These agents, if given in appropriate dosage, not only have the same effect as regards the lymphoid tissue, but they also produce the same general effect on the animals—they lose weight and die in a state of emaciation. Incidentally, it may be recalled that in this condition there are also degenerative changes in the semiferous tubules of the testis similar to those observed in avitaminosis.

Why two such apparently dissimilar causes should produce the same effects is a problem which we propose to investigate further. It is a remarkable fact that the specific atrophy of lymphoid tissue, whether produced by exposure to radiations or resulting from the absence of vitamins from the diet, should be associated with such a profound general effect on the nutrition of the animal. This fact indicates that lymphoid tissue fulfils a more important function in connexion with the nutrition of the animal than is generally recognised, and that the effect produced on the general nutritive condition of the animal by these different agencies may be due to their selective action on the lymphoid tissue. This suggestion finds confirmation in the following facts. It is known[5] that lymphocytes are concerned in the absorption and assimilation of fat, and experimental evidence has been presented[6] to show that the assimilation of protein from the intestinal canal is brought about partly by the agency of leucocytes. In certain marasmic conditions in children not due to interference with the food-supply there is an atrophy of the thymus and of the Peyer's patches, and no other lesion has so far been found to account for the condition.[7] In inanition the spleen is stated to be the organ showing the greatest atrophy.[8] This and an almost complete disappearance of the thymus has also been reported recently[9] as occurring in pigeons both in inanition and in experimental beri-beri. A systematic examination of the lymphoid organs generally in these various conditions does not appear to have been made.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

A NOTE ON
ARTIFICIAL RESPIRATION IN THE NEW-BORN.

By W. OSBORNE GREENWOOD, M.D. LEEDS, B.S. LOND.

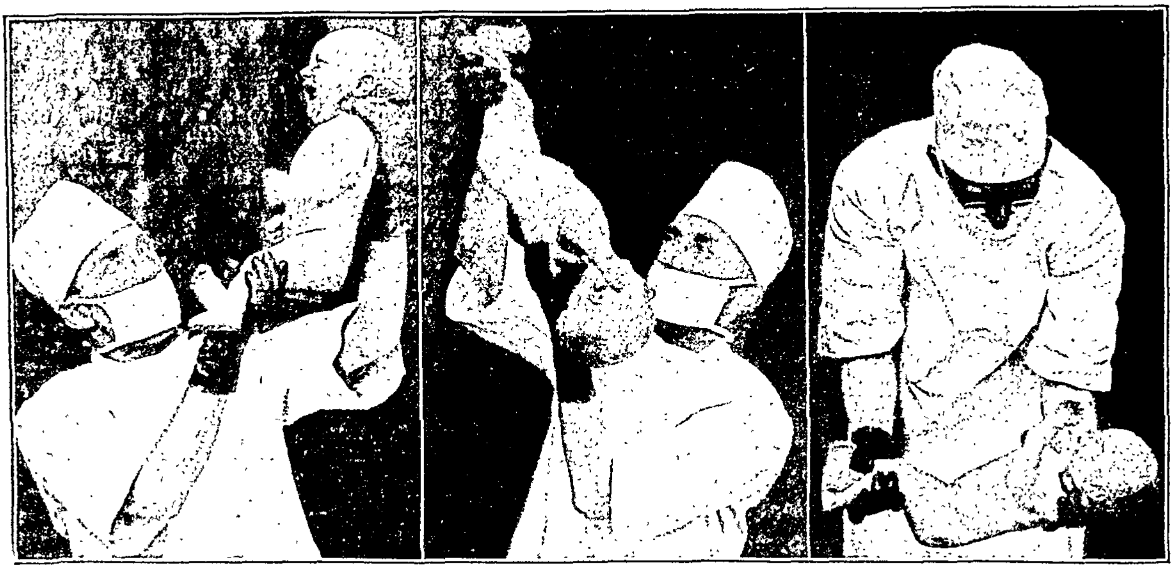
(*From the Acomb Nursing Home, Harrogate.*)

THE method of artificial respiration described below has proved, in my experience, more certain and effective than any of the methods now in vogue. I was led to investigate it by noting that a new-born infant who had inspired liquor amnii and was held head downwards emitted a sigh. This I supposed to be due to the pressure of the abdominal viscera on the diaphragm. As this is equivalent to expiration, I concluded that to hold the child in the reverse position would initiate inspiration.

To use the method the infant should be held in the following way:—

The back of its neck lies on the palmar surface of the operator's left hand, the occiput being supported in the hollow between the thumb and forefinger, so that the thumb and fingers grasp the mastoids. The right hand holds both ankles of the infant firmly from behind, so that the ulnar side is at the calves, the radial side at the ankles. The infant is held nearly vertical, say at an angle of 15°, and is then allowed to move quickly by its own weight downwards, feet first, about 2 feet. The abdominal viscera move down, the diaphragm is depressed and inspiration is at once initiated. The infant is now lifted, feet first, upwards and to the right of the operator and is therefore head downwards

Three Positions of the Infant in the Method of Artificial Respiration described by Dr. Greenwood.



First position, for movement downwards to imitate inspiration.

Second position, for movement downwards to imitate expiration.

Rest position between movements.

at an angle of 15° to the vertical. It is then moved quickly downwards, head first, about 2 feet. The abdominal contents fall against the diaphragm which is now pushed upwards (relatively to the child) and fully arched, and expiration is completed. The series of movements should be repeated some fifteen times a minute and the first attempt will often elicit a sigh if not a more pronounced response. Needless to say, any semblance of violence must be avoided.

As compared with Schultze's method it achieves exactly the same object—i.e., the abdominal viscera are made to arch and flatten the diaphragm alternately and to stimulate the heart as massage would do. Advantages over it are: As the infant is held firmly at each pole he is not so liable to slip; since the range of movement is not as great the cooling of the body surface must be less; it is not as violent; the gentleness of the movements are entirely under the control of the operator. Byrd's method and Marshall Hall's method consist in alternately flexing and extending the infant's body to the full extent: the former actively by holding both poles, then flexing and extending the spine; the latter passively by holding the infant horizontally on the palm of one hand, ventral surface downwards, then on the palm of the other hand, dorsal surface down, the head and lower limbs accomplishing flexion and extension by their own weights. Both methods are excellent for the milder grades of respiratory inhibition, but not as effective as the above for the severer ones.

Harrogate.

A CASE OF

ACETANILIDE POISONING; RECOVERY.

BY HASSAN EL ARCULLI, M.B. LIVERP.,
M.R.C.S., D.P.H.

A GIRL, aged 2 years, was brought to me on Sept. 4th, 1919, by her mother with the history of having ingested about 30 anti-influenza tablets some two hours before. It appeared that while the mother was engaged in some household duty the girl and her brother, aged 3 years, got hold of a box of these tablets. The boy sucked the sugar coating, and what remained was given to the girl, who swallowed it.

On examination the child appeared prostrated and somewhat cyanosed, especially around the mouth. Pulse feeble and irregular, its rate being 120; respirations 20. There was profuse sweating; temperature was 97° F. in the axilla. A provisional diagnosis of poisoning by some coal-tar derivative was made. An emetic of mustard and water was given and a saline purgative administered; these acted well, and the child when seen four hours later appeared less blue. The mother was instructed to keep her near a fire, and liq. strychninæ was given—♏ i. every two hours.

On the 7th the mother said that the girl was very irritable the night before and was inclined to arch her back. She reported that the cyanosis came in spasms; sometimes the colour was quite good, while at other times the face would be blue; the periods of cyanosis varied in duration from a few minutes to an hour. The knee-jerks were +.

Professor R. J. M. Buchanan was called into consultation and he gave a hopeful prognosis.

Acting on his advice the strychnine was temporarily stopped and brandy-and-soda given in its place. A couple of days later the child seemed quite normal between the spasms of cyanosis. When examined during an attack the heart sounds were found to be weak but regular; respiration was also regular. Strychnine was again exhibited, ♏ i. every four hours.

Meanwhile it had been ascertained from the manufacturing chemists that the tablets were made from: acetanilide, gr. i.; quinine sulphas, gr. ss; podophyllin, gr. $\frac{1}{10}$; camphor, gr. $\frac{1}{4}$.

On Sept. 11th bronchitis developed, and a measly rash appeared. The temperature, which had become normal on the day following the taking of the poison, rose to 101° F., and it was a question whether the rash was due to measles or to the effects of the acetanilide. It was, however, thought wiser to err on the safe side, so the child was isolated and she got over the complication in a few days. It was quite seven weeks before the cyanosis and sweating disappeared altogether. At no time was there any sign of methæmoglobinuria.

Apart from the treatment applied, the result may have been due to the presence of the other ingredients in the tablets, or the child may not have swallowed the large number alleged, although on this point the mother is quite firm in her belief.

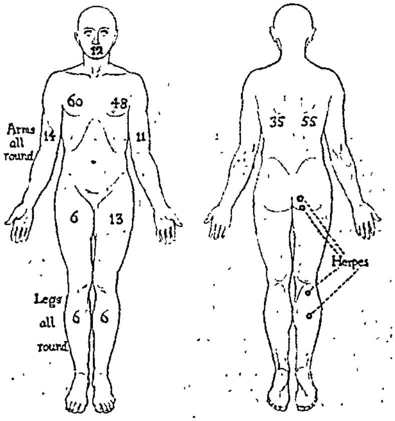
Liverpool.

A CASE OF ABERRANT HERPES.

BY G. DE BEC TURTLE, M.D. DURH., M.R.C.P. LOND.

THE differential diagnosis between varicella and herpes occasionally presents difficulty, and the following case appears of interest in this connexion:—

A gentleman, aged 71, consulted me for pain in the back and a skin eruption which had only been noticed a few hours. On examination there was a well-marked patch of herpes zoster on the right buttock and in addition a few vesicles were distributed over the body generally. There was no constitutional disturbance of any kind. On the following day there were four patches of herpes extending from the right buttock to the ankle, down the back of the thigh and knee. He was also covered with a distinct vesicular eruption very closely resembling that of varicella, several of the vesicles being umbilicated. For the sake of interest the vesicles were counted: they numbered 266 and were distributed as follows: 12 over the face and scalp, 103 on the trunk anteriorly, 90 on the trunk posteriorly, 14 on the right arm, 11 on the left arm, 12 on the right leg, and 19 on the left leg. There was none apparent on any mucous membrane.



The diagnosis rested between an attack of varicella occurring at the same time as the outbreak of herpes zoster in the leg and generalised or aberrant herpes, which I think the condition undoubtedly was. This view was shared by Dr. Graham Little, who saw the case in consultation with me. The condition cleared up quite quickly in a few days, simultaneously with the original patch of herpes zoster. There was no evidence of any case of varicella either before or after in the patient's house.

Cambridge-terrace, Hyde Park, W.

PRESENTATION TO A MEDICAL MAN.—On April 26th a presentation was made by the staff of King Edward's Building of the Post Office to Dr. S. B. Pennington on his transfer from the E.C. District Office to the Western District Office. Dr. Pennington was medical officer for the staff at King Edward's Building for seven years, and during that time earned the esteem of all grades of the manipulative staff for his considerate, sympathetic, and courteous treatment. The presentation consisted of a suit case and a cheque. The medical officers present included Dr. B. G. Connelly, Dr. A. Benson, Dr. H. Palmer, and Dr. H. H. Bashford.

Medical Societies.

BRISTOL MEDICO-CHIRURGICAL SOCIETY.

AT a meeting held on April 13th, with Dr. L. E. V. EVERY-CLAYTON, the President, in the chair, Mr. C. A. JOLL (London) gave an address on the

Surgery of the Thyroid Gland,

based on 432 cases operated on by himself and illustrated by a number of epidiascope pictures.

Discussing the ætiology of various forms of thyroid disease, he objected to the septic theory of the origin of exophthalmic goitre on the ground that there was no evidence to support it. He spoke of various forms of thyroiditis, alluding to the chronic "ligneous" thyroiditis of Riedel, and the possibility of mistaking it for malignant disease. The occasional association of adenomata with thyrotoxic symptoms, and the formation of adenomata within simple parenchymatous goitres, as well as the possibility of malignant changes within the latter, were touched upon. Turning to Graves's disease, Mr. Joll gave it as his opinion that it was to be distinguished from "non-hyperplastic toxic goitre," a distinction of importance in view of the smaller surgical risk of cases in the latter group. He laid stress on the relation between Graves's disease and progressive myocardial degeneration, speaking of the value of electrocardiography in tracing the course of the latter. Operation is, he said, indicated for any simple goitre causing pressure symptoms unless it respond quickly to other forms of treatment; also for simple goitre causing toxic symptoms and other forms of chronic ill-health. He claimed, further, that Graves's disease was curable only by early operation: saying, however, that patients with this disease, who did not wish to undergo operation, should not be pressed to do so, as such patients did not do well. The technique of operation was demonstrated by an admirable series of line drawings, and something was said as to the value of ligation of the superior thyroid artery as an alternative to thyroidectomy in certain cases. Local anæsthesia, Mr. Joll thought, was indicated only in the presence of much stridor or cardiac disease, or where the patient feared a general anæsthetic. On the other hand, general anæsthesia should never be deep, not more than enough to stop involuntary movement. Some of the difficulties and dangers of operation were discussed. Acute post-operative hyperthyroidism was, in the speaker's experience, a rare complication. He claimed that surgical treatment resulted in a cure of Graves's disease in 75 per cent. of the cases operated on. Recurrence of symptoms after operation was due to failure to remove enough of the gland.

The paper was followed by a discussion, in which the PRESIDENT, Mr. E. W. HEY GROVES, Professor F. H. EDGEWORTH, Dr. C. F. COOMBS, Mr. STUART V. STOCK, and Mr. J. LACY FIRTH joined.—In his reply Mr. JOLL said that he had never seen myxœdema follow thyroidectomy for Graves's disease.

NORWICH MEDICO-CHIRURGICAL SOCIETY.

Exhibition of Cases and Specimens.

A CLINICAL meeting of this Society was held at the Norfolk and Norwich Hospital on April 5th, Sir HAMILTON BALLANCE, the President, in the chair.

Dr. S. H. LONG showed a child who had had splenectomy performed for splenic anæmia, with excellent results. He also exhibited the spleen removed.

Dr. F. W. BURTON-FANNING read notes of a case of

Rat-bite Fever,

and demonstrated the points of interest on the patient. He remarked on the rarity of the disease, only 15 cases having been recorded in the British Isles, two of which had been under his care. The fever always followed on the bite of a rat or of an animal, such as a ferret or cat, which had been bitten by a rat. There was an incubation period after the bite, when the wound became re-inflamed and sloughy, but there was no formation of pus. The patient shown was bitten on the thumb, and an unhealthy sloughing wound was seen. Lymphangitis was a conspicuous feature and was followed by a rash which very much resembled a papular secondary syphilitic rash. The disease was caused by a spirochæte, which, however, had not been found on direct examination of the patient's blood, but was discovered when some of his blood had been injected into a white mouse. The fever was of intermittent type. As to treatment, quinine was found to be quite useless, and the only treatment of any value was the intravenous injection of novarsenobillon.

Mr. A. J. BLAXLAND showed the Pedunculated Intra-vesical Middle Lobe of a Prostate causing urinary obstruction, without hypertrophy of the lateral lobes, which he had removed from a man of 56 with complete relief to the symptoms. He also exhibited three specimens of the Pyloric Half of the Stomach, which he had excised for chronic ulceration. In his opinion this operation was more satisfactory than the usual one of excision of the ulcer by itself. It was easier to perform, there was practically no shock at the end of the operation, and the immediate after-results in his cases had been excellent.—The PRESIDENT said that Mr. Blaxland had raised a very important surgical question. He agreed as to the comparative simplicity of this operation, but he considered that for most small ulcers in an accessible position local excision did all that was required.

The PRESIDENT exhibited an Ovarian Tumour, weighing 10 lb., with a twisted pedicle, which he had removed from a woman of 51. A peculiar feature of the case was that he found an extensive thrombosis of the veins in the omentum. In order to deal adequately with this thrombosis it would have been necessary to remove several feet of the small intestine and its mesentery, and he decided not to interfere. No bad symptoms had occurred, and he therefore concluded that after the removal of the large twisted tumour the thrombosed condition of the veins subsided.

Dr. A. BURTON showed a specimen of Tubal Mole from a case of Ectopic Gestation of less than two months' duration.

Dr. A. J. CLEVELAND brought forward a case of Occupation Neurosis in a man, aged 28, who had worked in a boot factory, and developed a condition of pseudo-chorea. The right arm was chiefly affected. When the patient extended the arm to do anything it developed incoördinated movements, and the condition was so severe that the man was quite unable to work. Treatment seemed to have no effect, and in Dr. Cleveland's opinion the prognosis was very bad.

DEVON AND EXETER MEDICO-CHIRURGICAL SOCIETY.

A MEETING of this Society was held at the Royal Devon and Exeter Hospital on April 21st, Dr. W. GORDON in the chair.

Dr. F. A. ROPER read a paper on the

Nature and Treatment of Surgical Shock.

He first acknowledged the great help given to all who had specially to deal with this condition during the war by the reports of the Medical Research Committee and Third Army Shock Committee. After differentiating between primary and secondary shock, he went on to describe the blood changes in the latter condition found experimentally in animals by Dale, Laidlaw, Trevan, and Bainbridge, and also found in man. These were due to leakage in the capillary area, and accompanied by fall of blood pressure, cold being a further important factor in producing stagnation. An invariable result of this stagnation, leading to deficient intracellular oxidation, is acidosis. The defect of the adrenalin theory of shock is that shock is often fully developed long before sympathetic adrenalin exhaustion can have occurred. This leads to the consideration of other possible factors, first and foremost the respiratory exchange. The automatic compensating acidosis postulated by the acapnia theory might well be at least a considerable additional factor, in view of the well-known observation that acids dilate peripheral vessels. Cannon's experiment of clamping the aorta and observing the resulting acidosis and shock on removal of the clamp was corroborative and should be remembered in using the tourniquet. There was, lastly, considerable similarity between the reaction of the body towards infection and towards injury by violence. Dr. Roper showed that, as regards treatment, it was important to draw a sharp distinction between hæmorrhage and shock, best distinguished in doubtful cases by the use of the hæmoglobinometer. Dr. Roper advocated the method of "forced fluids" in the treatment of shock, and spoke of the advantages of Bayliss's 6 per cent. gum acacia solution in normal saline in largely obviating leakage from the circulation. No striking results seemed to be obtained by use of alkaline solutions, but the consensus was that these were of benefit in acid-forming toxæmias resembling shock. Blood transfusion was of great value in shock, but results were not so striking as in hæmorrhage. In Dr. Roper's opinion the citrate method was to be preferred. He urged the advantages of nitrous oxide and oxygen anæsthesia in obviating further shock due to fall of blood pressure during or after operation, and envisaged the possibilities of future progress in successful treatment on the lines of keeping up the CO_2 tension in the blood by administering a proportion of CO_2 in the respired atmosphere at least equal to its normal alveolar tension. In judging as to fitness for operation the estimation of the blood pressure was a valuable guide.

Discussion.

The PRESIDENT asked Dr. Roper what opinion he had formed as to the value of pituitrin in these cases and as to the maximum period of time that it was possible to keep the patient under with $N_2O + O$ as the sole anæsthetic.

Mr. A. L. CANDLER discussed the apparently contradictory statements with regard to acidosis, which was stated to be a stimulant to the respiratory centre, and the giving of soda, which also had a beneficial effect in cases of shock. In regard to shock from loss of blood (where the treatment was obviously different from that called for in shock caused by other conditions) Mr. Candler emphasised the importance of the rate of flow rather than the volume of blood lost as the causal factor in the production of shock. He also advocated the cleaning of burns under an anæsthetic as soon as possible and the removal of destroyed tissues, thereby diminishing the liability to subsequent absorption of a large amount of toxin. Shock following the removal of a tourniquet was to him a clear indication of what happened when the patient was not safeguarded from a sudden rush of toxin into the circulation. Mr. Candler had seen no benefit from pituitrin in the treatment of shock, although he recognised its value as a promoter of intestinal activity.

Dr. J. SHIRLEY STEELE-PERKINS advocated gas and oxygen as a general anæsthetic, given a reliable apparatus with an efficient regulator.

Dr. R. V. SOLLY discussed the question of acidosis and its production in chloroform narcosis.

Mr. NORMAN LOCK considered that the condition of shock was far more complicated than a mere acidosis, as soda was of little more use than saline. Given an increased viscosity, as by gelatin injections, the saline does not rush in and out and tension is repaired in the circulation.

Dr. ROPER, in his reply, considered that there was no practical time limit in the giving of N_2O and oxygen as a general anæsthetic. He was not in favour of an anæsthetic such as ether in burns where shock was often present. He also spoke of the reducing effect on the hæmoglobin content of the red blood cell when either chloroform or ether were employed as anæsthetics. Boyle's apparatus had proved very serviceable at the C.C.S. to which he was attached in France. Replying to Mr. Lock, histamine was the acid substance actually causing acidosis.

ROYAL MEDICO-CHIRURGICAL SOCIETY OF GLASGOW.

A MEETING of this Society was held in the Faculty Hall, Glasgow, on April 1st, when Dr. JAMES H. MARTIN made a communication on

A Series of 50 Consecutive Cæsarean Sections without Fatality.

Dr. Martin opened by referring to his technique in this operation, which was a modification of that introduced by Professor Murdoch Cameron. His incisions are made about an inch and a half to the right of the middle line, two-thirds being above the level of the umbilicus. This utilisation of the rectus and its sheath prevents a subsequent hernia. There is the further advantage that as a rule this abdominal incision brings the operator right down on the middle line of the uterus. In making the uterine incision Dr. Martin always uses a metal pessary, oval in shape and slightly concave, as suggested by Professor Cameron. In removing the placenta and membranes he turns the uterus inside out. Thus the uterine arteries are kinked and the loss of blood is infinitesimal. The wall of the cavity of the uterus is now rubbed thoroughly with gauze, which may be termed a curettage. The difficulty in removing the membranes in the region of the os is lessened by sweeping the finger round beyond the internal os while the patient is being prepared for operation.

In suturing the uterine wound the lowest suture is inserted and tied before the uterus is turned inside in, and this seems to lessen the hæmorrhage while the other sutures are being inserted and tied, particularly if the uterine arteries are not well compressed. The sutures are of silk and interrupted. If the patient is not sterilised mattress sutures of catgut are usually inserted along the uterine incision, the peritoneum, and to some degree the superficial muscle, being included in these mattress sutures. The peritoneum and posterior sheath of rectus muscle are sutured together with a fine continuous catgut suture, and five or six silkworm gut sutures are inserted through skin and anterior sheath of the rectus, but not tied. The anterior sheath of the rectus muscle is now sutured with a continuous catgut suture and the skin approximated by another continuous catgut suture. After cleansing the wound and surrounding skin a gauze pad is applied and anchored by tying the five or six silkworm gut sutures referred to above. Gamgee tissue is applied and fixed with 6 in. bandages. After the operation the patient is propped up in the sitting posture before being completely round from the anæsthetic. The advantage of this posture is that the lochia when shed flows through the cervical canal into the vagina and on to the pad, and is not retained in the uterus. Further, micturition and defæcation are not difficult in this position.

Dr. SAMUEL J. CAMERON made a communication on the Surgical Treatment of Uterine Prolapse.

Reviews and Notices of Books.

COLLECTED PAPERS OF THE MAYO CLINIC.

Edited by Mrs. M. H. MELLISH. Vol. XI., 1919. London and Philadelphia: W. B. Saunders Company. 1920. Pp. 1331. £3.

IN reviewing the eleventh annual volume of the collected papers of the Mayo Clinic, Rochester, Minnesota, it is tempting to discuss, instead of the contents of the book, the organisation of the great clinical machine which produced it. The methods of the Clinic are, however, too well known to need further publicity, and the matter in the book covers such an enormous field that to attempt to appraise its value is quite a sufficient task. A volume of miscellaneous papers by numerous contributors can with difficulty avoid the imputation of "scrappiness," but in the present case the number of papers is large enough to permit of their being to some extent grouped under regional headings, so that each division gives a more or less comprehensive view of the lessons that have been learnt during the year.

The first and most important section deals with the surgery of the alimentary canal, and is restricted chiefly to problems connected with the stomach, duodenum, and gall-bladder. The cause of gastric and duodenal ulcers is sought for by means of an anatomical study of the arteries supplying them, and the conclusion is reached that the disposition of the vessels along the lesser curvature and the first inch of the duodenum is such as to favour the occurrence of thrombosis. There is no conclusive evidence that ulcers are in this way "explained," but the demonstration is suggestive. Another paper deals with the estimation of the "operability" of carcinoma of the stomach by means of the X rays, but in view of the difficulty in any early case of making a definite diagnosis of the presence of the disease it is evident that this determination of operability admits only of a limited application. Dr. C. H. Mayo discusses the technique of the surgical treatment of carcinoma of the stomach by gastrectomy, and brings up to date his survey of the work done; his results show a recent increase in the percentage of three-year cures obtained and are so far satisfactory. Another important paper deals with the subject of the diagnosis of gastro-jejunal ulcer following treatment by gastro-enterostomy, and the opinion is expressed that it is usually due to a mishap in the operative technique, thus confirming the conclusions of other surgeons. The most interesting paper of all on the stomach is by Dr. D. C. Balfour, who discusses the treatment of the "bleeding type" of ulcer. He seeks to demonstrate that hæmorrhage commonly occurs after a curative operation has been performed, and believes that the treatment should always include the removal of the ulcer, preferably by excision with the cautery. The remainder of this section deals chiefly with biliary problems, special attention being given to the anatomy and functions of the sphincter of the common bile-duct or papillary muscle of Oddi.

The second section, on the urogenital organs, contains papers on most of the current problems of this region—the dangers of pyelography, the prognosis of renal tuberculosis, the removal of stones from the ureter, and other subjects too numerous to mention. This section also contains, somewhat unaccountably, several papers on the thyroid gland and its functions, and one on the effect of splenectomy on the thymus. It is, at any rate, an indication of the trend of opinion that these organs should be classed as "urogenital." The papers on the thyroid gland include an elaborate investigation of the chemical properties of its active principle, thyroxin, and an important contribution towards the understanding of the clinical value of the "basal metabolic rate" in exophthalmic goitre. With this valuable method of gaining precise knowledge as to the results of operative treatment we dealt in some detail last week (pp. 915 and 921). A smaller section on the blood contains an extremely interesting account of an attempt to determine the length of life enjoyed by transfused corpuscles by means of differential agglutination of mixed corpuscles belonging to more than one blood group. This is one of the most scientifically satisfying of all the papers in the book.

The remaining sections deal with a somewhat heterogeneous collection of subjects, which it is impossible to summarise in a few words. They range from tuberculosis of the spine and epithelioma of the lip (this is an instructive study based on 537 cases), to the surgical treatment of bunions and the best method of sharpening a scalpel. There is matter here for everyone and, if some of the papers are so slight as to have been hardly worth reprinting, many more are really solid contributions to surgical science, and the book as a whole bears eloquent testimony to the activity and to the admirably scientific attitude of the workers in the Mayo Clinic.

MEDICINE AND DISEASE.

Die Konstitutionelle Disposition zu Inneren Krankheiten. Second edition. Von Dr. JULIUS BAUER. Berlin: Julius Springer. 1921. With 63 illustrations. Pp. 650. M.88.

MODERN advances in medical science have altered our conception of ætiology, and causative factors of disease have occupied an increasing share of medical interest. Particularly in those morbid processes that result from specific bacterial infection, the ætiological riddle has seemed to be solved when a microbe, more or less obeying Koch's postulates in relation to the disease, has been isolated. The host's susceptibility and resistance to infection have not indeed been forgotten, as the important mass of work on the subject of immunology bears witness; nevertheless the soil has been somewhat neglected for the seed. In terms of practical medicine it may be said without much exaggeration, that interest has shifted from the patient to his disease, and this tendency has been strengthened by modern discovery in specific therapy; thus treatment has tended to make the same change in direction, and diphtheria, for instance, is treated with serum and the patient with contempt.

In the present volume Dr. Julius Bauer creates a new departure in medicine in presenting an instructive and important systematic treatise on the part played by constitutional states in the pathogenesis of disease, a thesis which he carries to the length of defining a "konstitutionspathologie." The opening chapters deal with the broader aspects of the subject and define the words employed; there is thus introduced an interesting discussion on diathesis, dyscrasia, and inheritance. Infantilism, precocity, senility, and progeria are other matters of interest discussed in these chapters, and the author crystallises his ideas so far as to give illustrations in diagram of the several recognised constitutional types—namely, the respiratory, digestive, muscular, and cerebral constitutions; photographs of patients illustrating these types are also given. It is impossible to describe at all adequately the great mass of information assembled in respect of the constitutional aspects of clinical disorders, diseases, abnormalities, and developmental defects. The rarest curiosities naturally claim a rather disproportionate notice, but some idea of the scope of the work is indicated by the fact that there are more than 4000 references to the literature.

We have no hesitation in recommending this book as a valuable work of reference, both on account of the information it provides and on account of the weight it adds to the constitutional aspect of disease.

The Medical Treatment of Disease. By ROBERT DAWSON RUDOLF, C.B.E., M.D. Edin., F.R.C.P. University of Toronto Press. 1921. Pp. 457.

THIS book, written for students and young practitioners of medicine, is presented in a readable and attractive form. The general arrangement of the subject-matter is good and systematical, so that it is easy to find at once any information required. An author incurs a great responsibility in advising definite forms of treatment to students and young practitioners unless the treatment advocated is well known and well tried. On this account the book is open to some criticism, for it includes reference to treatment that has hardly passed beyond the experimental stage. For instance, auto-serum therapy (intrathecal injection) is mentioned in the treatment of chorea, though the advisability of tonsillectomy is not discussed in either chorea or rheumatic fever; in the treatment of gastric ulcer it would have been better to give the Lenhartz diet in detail than to discuss duodenal feeding at relative length; it is possible that scarlet fever is due to a streptococcal infection, but, if it is, the type of infecting streptococcus has not yet been established, and it is premature to advise students to use vaccines as a prophylactic against this disease. These examples could be multiplied. Dr. Rudolf has made too great sacrifices in the effort to make the book up to date. In the doses of drugs recommended the author shows good judgment. Exception must, however, be taken to the dose of adrenalin chloride advised for hypodermic injection in the treatment of a paroxysm of asthma; 8 to 15 minims is too large an initial dose, since some persons are susceptible to the drug.

A simple book on treatment is sure of a place in the general practitioner's library, and the second edition of this book may fill that place. If it were revised by someone engaged in general practice certain of the more common and difficult aspects of medicine might be expanded and space found in the section on insomnia, for instance, for the sleeplessness that results from acidity, flatulence, or constipation.

PRINCIPLES OF GENERAL PHYSIOLOGY.

Third edition, revised. By WILLIAM MADDOCK BAYLISS, M.A., D.Sc., F.R.S., Professor of General Physiology in University College, London. With 261 illustrations. London: Longmans, Green and Co. 1920. Pp. 862. 28s.

OUR opinion, expressed when this work was first published, that it is "a most interesting, erudite, and comprehensive treatise" is unchanged, and we are glad to offer an equally cordial welcome to its third edition. The number of pages in the present edition only exceeds that in the first by a dozen or so. In the sections rewritten for the second edition (published in 1917)—e.g., activity of muscle, kidney and the visceral system, and transport of carbon dioxide in the blood—no great changes have been found necessary. But a notable addition is a section on the capillary circulation (p. 704 *et seq.*), with regard to which important work has recently been published. Krogh (1919 and 1920) gave experimental evidence that the capillaries can be affected independently of the arterioles, while more complete proof of the independent contractility and dilatation of the capillaries was given by Dale and Richards in 1918, including the observations of Dale and Laidlaw on the effects of the base histamine. In the same section "wound shock and traumatic toxæmia" is dealt with. Wounded men in the late war often showed the signs of great loss of blood, although the actual hæmorrhage may not have been at all severe. Evidence of various kinds pointed to the probability that the injured tissues were producing some toxic substances. Although the toxic products from injured tissue have not been actually identified, they have the same physiological action as histamine—that is, a widespread dilatation of the capillaries leading to a pooling of blood and its withdrawal from the effective circulation, with all the serious results of a failure of blood-supply to vital organs. Experience has shown that the maintenance of a normal blood volume is of the greatest moment. Dilution of the blood up to very wide limits is of comparatively little significance so long as its volume is normal (p. 707).

Professor Bayliss utters a timely observation that in regard to medical education "there is some need to guard against too narrow an interpretation of what is supposed to be of direct application to clinical practice. What is at the present time looked upon as pure abstract or academic science may turn out next week to be of vital importance. Take, for instance, the electrical phenomena of cell activity and their application in the electrocardiograms." Without undervaluing what is done under the direction of another mind, Bayliss points out that the greater number of the fundamental discoveries in physiology were made by men who were able to direct their work in the way suggested by its actual progress.

DIAGNOSIS.

Diagnostische Winke für die tägliche Praxis. Second edition. Von Dr. E. GRAETZER. Berlin: S. Karger. 1920. Pp. 264. M.16.

THE object of this handbook is to give a short description of the atypical forms in which common diseases frequently appear in general practice. It is recognised that disease often fails to don its text-book garb, and thus may escape recognition by those without much clinical experience. The diseases are arranged in alphabetical order and there is a good index. A short account is given of the onset and of the cardinal signs and symptoms of each disease. Then follows a brief description of the various courses it may take, a list of atypical and occasional symptoms, and finally the differential diagnoses. The object is admirable, but the subject is too difficult for compression into so small a compass. The cardinal signs are not always well chosen, and in the case of rheumatic fever, for instance, there is no mention of valvular disease in the typical picture. The only method that a practitioner has of recognising atypical forms of disease is to know the whole of medicine thoroughly, and a book which sets out to describe only the less common forms which disease may take cannot be of much assistance to him.

Lehrbuch der Differentialdiagnose innerer Krankheiten. Second edition. Von Professor Dr. M. MATTHES, Direktor der Medizinischen Universitäts-Klinik in Königsberg. Berlin: Julius Springer. 1921. With 106 plates. Pp. 621. M.68.

THIS book is written for recently qualified practitioners with the object of providing a bird's-eye view of differential diagnosis. The subject is arranged in sections. The first two deal with fevers, and one or more are allotted to diseases of the respiratory, circulatory, alimentary, and renal systems; diseases of the spleen, liver and gall-bladder, blood, joints, and bones are dealt with in separate sections. Apart from the differential diagnosis of meningitis and meningism and of neuralgia the central nervous system is not included, being reserved for a separate volume. The book is written from a strictly clinical standpoint, and the author makes his attitude clear in the statement that a man's clinical experience may be judged by the history he takes of his patients' cases. The several sections are similarly dealt with on the following lines; thus in disease of the alimentary tract the disorders of this system that complicate disease elsewhere are referred to; a discussion of the major symptoms of gastro-intestinal disorders follows; and lastly the differential diagnosis of clinically recognised complaints is dealt with. Methods of clinical investigation are discussed and reviewed, and here the author sometimes passes beyond the limits of ordinary clinical practice, and includes methods that are only possible in the hands of experts in an institution where the necessary facilities are provided. In certain directions purely academic problems are considered at length; for instance, much information on the classification of the several forms of nephritis has been collected, but a want of discriminative criticism mars the value of this part of these sections. German authors are frequently mentioned, but no references are given, and though a few American and English workers are named it is evident that the author is not familiar with their writings.

The value of Professor Matthes's book to those for whom it is actually intended lies in the simultaneous discussion of a subject from the point of view of symptoms, clinical syndromes, and methods of clinical examination; there is a good index guiding the reader quickly to the desired context. But it is likely to prove of most interest to those who are engaged not in the practice alone but also in the teaching of medicine.

NOTES ON MIDWIFERY.

Second edition. By J. M. MUNRO KERR, M.D., and JAMES HENDRY, M.A., B.Sc., M.B. Glasgow: Maclehose, Jackson, and Co. 1920. Illustrated. Pp. 156. 10*s.* 6*d.*

THIS book consists of a synopsis of notes of lectures delivered at Anderson's College Medical School. It is interleaved so that the notes may be amplified and added to by the student. Necessarily short and somewhat compressed, it yet forms a sound basis for the student to ground his reading upon and a ready reminder to the teacher of the main heads of the subject. Dr. Munro Kerr's authority gives the book a considerable value, and we need hardly add that the teaching is thoroughly practical and sound. If used as it is intended, the book should prove of value to the student, both in giving the main outlines of the subject in a clear form and in enabling him to revise and coördinate his knowledge from the point of view of examinations.

THE PRACTICE OF MEDICINE.

Fourteenth Edition. By Professor JAMES M. ANDERS, M.D., Ph.D., LL.D., with the assistance of Dr. JOHN H. MUSSER, Jun., B.S., M.D. London and Philadelphia: W. B. Saunders Company. 1920. Pp. 1284. 45*s.*

NEW editions have followed each other in quick succession since the original publication in 1897 of this text-book, and in bringing out this, the fourteenth edition, Professor Anders has had the assistance of Dr. J. H. Musser. The subject-matter is brought well up to date and contains several entirely new sections; those describing bronchial spirochætosis, trench nephritis, disordered action of the heart, epidemic encephalitis, and botulism deserve mention, while the references to the estimation of basal metabolism in exophthalmic goitre and to splenectomy in pernicious anæmia afford further evidence that recent advances have not been ignored. The article on focal sepsis is suggestive, and new and important points are considered in the sections on pneumonia, pellagra, scurvy, hæmolytic jaundice, Banti's disease, and asthma. The methods of examination of the efficiency of the stomach, intestines, and kidneys are discussed, and in view of the increasing need in accurate diagnosis of these clinico-pathologic aspects of investigation we hope that sufficient advance will have been made to justify a separate description of hepatic and pancreatic function tests in the next edition. With regard to renal function tests reference might have been made to globulinuria in functional proteinuria and to the diastase test. Professor Anders has succeeded in maintaining the position of his work as a first-class standard book of reference in practical medicine, and the reader will find in it the assistance he requires for the detailed study and diagnosis of disease.

MAN'S DESCENT FROM THE GODS.

The Complete Case against Prohibition. By ANTHONY M. LUDOVICI. London: William Heinemann. 1921. Pp. 254. 14s.

THIS is a most amusing book; it contains a good deal of sound sense, and also, we must add, a good deal of nonsense. The author holds that the myth of Prometheus is a tradition of an actual event in the history of the ancestors of the ancient Greeks. These ancestors (who were the gods of the ancient Greeks) were probably the Cro-Magnon race; they were acquainted with fire and its uses, but it was only used under certain restrictions. Prometheus obtained the secret of making fire and demonstrated it to the inferior races—i.e., the men with whom the gods mingled. Hence arose all the appalling consequences due to the cooking of food, and not until Dionysus the Saviour arose with his fermented liquors were these deleterious consequences checked. Prometheus versus Dionysus is thus the theme of the book. Now, putting aside the fancifulness of this thesis, it is perfectly true that cooking certain kinds of food does damage their value, and thrice-cooked food may be worse than once-cooked food. It is also true that liquors prepared from fermented and germinated cereals have an antiscorbutic property—a property which is found in old-fashioned ale and to a less extent in modern beers. But cooking has its virtues, and even Mr. Ludovici agrees that meat should be cooked—that is to say, lightly roasted or grilled; it is cheering to think that the immortal essay on Roast Pig is still to be a watchword for epicures—

> "There is no flavour comparable, I will contend, to that of the crisp, tawny, well-watched, not over-roasted *crackling*, as it is well called—the very teeth are invited to their share of the pleasure at this banquet in overcoming the coy brittle resistance. ...... "

Ale, too; as we read Mr. Ludovici's praise of ale we seem transported to the age of good Bishop Still, who wrote that feeling passage—

> "I cannot eat but little meat
> My stomach is not good,
> But I do think that I can drink
> With any that wears a hood;
> Back and side go bare, go bare,
> Both hand and *foot go cold*,
> But belly, God send thee good ale enough
> Whether it be new or old."

So far we can go with Mr. Ludovici, and we also agree with his strictures upon some of the evils of industrialism, which came to their zenith in the first half of the last century. But his chapter on Eve and Pandora is a mistake. If some women are fools, have no taste, and have a lust for petty power, the same things may be said of some men. If some women mate with undesirable men, so also do some men mate with undesirable women, but to say, in Mr. Ludovici's words, that woman "becomes associated with a decent man only by accident" is silly.

QUAKER ASPECTS OF TRUTH.

By E. VIPONT BROWN, M.D. Lond. London: The Swarthmore Press. Pp. 156. 5s.

THIS book consists of a series of addresses designed to show the superiority of the Quaker system of religion over other systems of Christianity. With the author's contention that all forms of orthodox Christianity have departed from the principles of primitive Christianity, or, at least, do not carry them out, we can agree, but we should say that even the Quakers do not carry out primitive Christianity in its entirety. It is no business of ours to decide for or against Quakerism as opposed to other forms of religion, but we must point out one or two places where Dr. Brown is inaccurate. For instance, in his chapter upon Christianity and War he insists upon saying that "during the first two centuries of our era Christians consistently refused to carry arms." Some Christians undoubtedly did, and that because their religion forbade them to kill. But the chief reason why Christians refused to serve was on account of the impossibility of so doing without recognising, or seeming to recognise, the divinity of the heathen gods. All the same, there were many Christians in the army, as such stories as that of The Thundering Legion, under Marcus Aurelius, circa A.D. 169, and the martyrdom of the Thebæan Legion, at the order of Maximian, A.D. 285, show. We say nothing for the truth or otherwise of the story of the miraculous thunderstorm, or of the martyrdom, but the mere fact of the existence of the legends shows that Christianity in the army was quite common. Again, on p. 60 Dr. Brown is arguing as to the uselessness of creeds, confessions of belief, and so on, and in mentioning other denominations, says of creeds, "When these have been understood and believed and accepted as true, then salvation is assured; the end of religion has been attained." This statement is simply not correct.

JOURNALS.

Brain. Vol. XLIII., Part IV.—Left-handedness and Mirror-writing, especially among Defective Children, by Hugh Gordon. A record of tests carried out on children in "special schools" in London and Middlesex. The tests described were found to be those giving the most consistent results. It was found that whereas in the ordinary elementary schools the percentage of left-handedness was 7·3, in the special schools it was 18·2. In those schools defects of speech occur more frequently in left-handed than right-handed children. In the case of twins, when one is left-handed and the other right-handed, the former is frequently backward or even in a "special" school, the latter normal. Among normal children the left-handed are frequently the most efficient and capable; among the mental defectives it is exactly the reverse. The percentage of mirror-writers is much higher in special schools and in them among the left-handed (30 per cent.) than the right-handed (2·2). The percentage of mirror-writers among left-handed children who write with the right hand is found to be: boys, 32 per cent.; girls, 62 per cent. Many other interesting observations on mirror-writing are given, and the author suggests, as the only possible hypothesis at present, that in these children "something has occurred which has interfered with the proper functioning of the dominant hemisphere."—Tonus and the Reflexes, by J. K. A. Wertheim Salomonson. A description of a part of the author's investigations by means of Einthoven's string galvanometer of the nature of muscular contraction. Three groups of contractions can be differentiated: (1) the simple muscle twitch, characterised by its short duration and by its being preceded by a double-phase action current; (2) those characterised by a current of action in the form of a rather irregular alternating current with a frequency of about 50 periods per second—e.g., all voluntary contractions, epileptic convulsions, and all cutaneous reflexes; (3) all kinds of muscular action in which no electric current of action can be detected—all changes in muscle tone occur in this way, as also all spasms of spastic muscles. The method applied to the reflexes shows that these are much more complicated than is generally supposed to be the case. The complication arises from the fact that every simple or tetanic reflex is in itself the cause of a secondary tonic reflex, and most are governed by more than one centre. The simple twitch of the knee-jerk is often succeeded by a tonic contraction, which the author holds is conditioned by a reflex path through the sympathetic and Boeke's fibres. In addition, the varieties of knee-jerk seen in chorea and in Westphal's "pseudo-knee-jerk" can only be explained by assuming the existence of a third cerebral centre. The cutaneous reflexes have two centres, one spinal, the other cerebral. In man the latter is much the more important. The plantar response is fully considered; toe-extension is the primary, protective, spinal reflex; toe-flexion is a late developed, cerebral reflex, needed for standing and walking, which in the adult supplants the former. When the pyramidal tract is affected, not only is the cerebral centre put out of action, with consequent reappearance of the toe-extension (spinal) reflex, but the irritability of the spinal centre governing the secondary tonus reflex is increased which produces ample extension of the toe.—Aphasia: An Historical Review (the Hughlings Jackson Lecture for 1920), by Henry Head. The first serious contribution to our knowledge was furnished by Gall at the beginning of the nineteenth century; he localised six forms of memory in separate "organs" or "centres" in the frontal lobes. In 1861 Broca published the case which was to become classical; he divided central affections of speech into the two groups "aphemia" and "verbal amnesia," and localised the lesion causing the former in the third frontal convolution. In 1864 Hughlings Jackson published his first paper. The basis of his treatment of the subject was that it is the power to form propositions that is affected, and not the memory of words or faculty of language; the higher the propositional value of the task the patient is asked to carry out the less he will be able to respond. The teaching of Jackson remained without fruit, first, owing to the profundity of its thought; and secondly, owing to the rise of a succession of brilliant dogmatists, led by Bastian, who propounded schemes and diagrams which gave apparently simple explanations of the phenomena. Recognition of the fact that it was only by twisting of the clinical findings that a case could be fitted into any particular scheme resulted in the publication in 1906 by Pierre Marie of his "Revision of the Question of Aphasia." He maintains that the aphasia of Broca was a combination of two distinct troubles, anarthria and aphasia, the former being simply inability or difficulty of articulating words without any defect of internal language, the latter corresponding to the "sensory aphasia" of Wernicke, which term should disappear. There followed the great discussion at Paris in June, 1908, which resolved itself mainly into a verbal battle without any real advance. Having closely studied the writings of Jackson, devised a new method of examination, and applied it to a large number of cases, Head propounds a new classification of these "disorders of symbolic thinking and expression," claiming that the observed facts show disturbance of these higher psychological processes and not of particular physiological functions subserving speech. The diagram makers worked on the assumption that we think in words; Jackson and Head maintain that we think in symbols, ranging from simple matching of two sensory patterns to recognition of abstract propositions.—The number closes with a discussion on Aphasia at the Royal Society of Medicine, in which Dr. J. Collier, Sir James Purves Stewart, Dr. Kinnier Wilson, Mr. Herbert Parsons, Dr. Stanley Barnes, and Dr. Head took part.

IN the *Military Surgeon* for March Lieutenant-Colonel E. E. Irons, Medical Corps, U.S. Army, discusses in a long and valuable paper the pneumonia which, in the last four months of 1918, followed influenza in the camps in the United States. There were more than 365,000 cases of influenza, and some 20,000 deaths. The case mortality of this pneumonia varied between 6 and 11 per cent. In one camp of 35,000 men the mortality during seven weeks was 3 per cent. of the total force. Influenza, also the complicating pneumonia, attacked more heavily the recruits and men from country districts. To struggle against the disease, or to attempt to carry on in spite of it, was dangerous. Hence non-commissioned officers and regular army nurses had a high mortality. On the other hand, there was little pneumonia amongst patients already in hospital who were attacked with influenza. The essential pathological condition produced in the lung by influenza was an enormous œdema with little consolidation, and many hæmorrhages due to necrosis of the interalveolar capillaries. No bacillus was at this stage recognised, but influenza lowered resistance and gave opportunity to the infections already in the naso-pharynx to develop, and so set up pneumonia. The microbic character of the pneumonia varied from camp to camp and period to period. Colonel Irons describes the morbid anatomy of the pneumonia, differing as it was due to pneumococcus, streptococcus, Pfeiffer, or staphylococcus. Tuberculosis as a sequel was rare. The best treatment proved to be early rest in bed, good nursing, and the prevention of complicating infection. No routine treatment could be advised. Convalescence was prolonged. Convalescents got double rations, and being still hungry were given bacon and beans additional. They were put through graduated exercises, beginning with a short five-minute walk twice a day, and went on to games and hard work. Care was taken that they were not discharged too soon, for their resistant powers had been severely taxed. A paper by Captain Ivy A. Pelzman discusses the high venereal rate of the U.S. Army in China. Of 100 men, 89 risk infection and 23 get it. Why? Prophylactic treatment in Tientsin is a long way from the centre of the town, and it is therefore proposed that tolerated houses be established on the U.S. Concession. The women would be kept clean, and prophylactic measures would be close at hand for the men, and there would be a lower venereal rate.—There is a most entertaining article, Doctors in Uniform, by Dr. H. W. Dana, of Boston, Massachusetts, giving account of the experiences and training of civil practitioners called up for the war. He tells of the difficulty there was in getting special chances of leave and the excuses that were not accepted. "Grandmothers' funerals did not go," he says. One doctor who arrived with a black umbrella was induced to travel three miles to exchange it with a quartermaster for another in a regulation khaki shade. The drill was beneficial, the discipline was improving, and the post-graduate special courses were wonderful. One candidate for a commission asked to mention intestinal parasites could only mention two—typhoid and paratyphoid. Dr. Dana is certain that no man who went to the Medical Officers' Training Camp left camp without getting vast benefit physically and professionally. Many officers have apparently been writing at Christmas from the United States to Sir John Goodwin, the Director-General of the Army Medical Service, and he has sent them a letter of thanks addressed to Surgeon-General M. W. Ireland, at Washington, recalling how generously their service supported us in 1917, and how much the support and help of those 1000 medical officers and 700 nurses meant to our armies.

New Inventions.

A URETHRAL AND SINUS DRAINAGE BOUGIE.

BEING interested in the treatment of gonorrhœa as practised by the Australian medical officers at Codford Camp I have had made for me a drainage bougie with a view of improving the technique. It is simply a tubular mesh of white silk closed at one end (see figure) through the centre of which runs a thin vegetable fibre. Its length is about 8 inches, the central core being several inches longer and its flexibility allows easy insertion into the urethra or sinus. Its mode of application is painless. The urethra being cleared by urination a sterilised urethroscope tube with the pilot is inserted; the pilot is then withdrawn and the drainage bougie saturated with any desired solution, such as permanganate of potash, protargol, acriflavine, and so forth, is introduced. The urethroscopic tube is now withdrawn leaving the drain in situ. Finally, the central core is pulled out, leaving the drainage-tube in the urethra. The drain gives no discomfort and is well tolerated. The advantage of this form of treatment is that all parts of the mucous lining come into contact with the antiseptic employed and there is no risk, as in syringing, of driving the pus into the posterior urethra, which I believe is a common cause of cystitis, prostatitis, and orchitis. I can conceive no more rational treatment of gonorrhœa than by the employment of this method. I have treated several cases with excellent results, but the number is too small for statistical purposes. I am having a glass endoscopic tube made for introducing the drainage-tube which could be used by the patient. This method might also be employed for the drainage of small sinuses, fistulæ, and for other purposes.

The silk bougies have been made for me by the Aurorascope Co., Ltd., Fulwood House, Fulwood-place, Holborn, W.C.

HENRY DUTCH,
Berkeley-street, W. M.D., M.R.C.S., L.R.C.P.Lond.

A TUBE FOR BLADDER DRAINAGE.

IT has always appeared to me that the methods of bladder drainage commonly employed after cystotomy are a reproach to surgery, and that if the care exercised in the modern theatre was extended to the obtaining of a water-tight and aseptic bladder the results of vesical surgery would be much improved. The usual method of placing a stout tube in the bladder and sewing the incision around it permits the bladder to retract into the pelvis, and invariably allows leakage around the sides of the tube, and contamination of the prevesical space. In some cases the tube presses painfully on the trigone and tenesmus results. In a few, I imagine, the bladder withdraws itself over the end of the tube; in any case prevesical infection is common and ammoniacal decomposition and deposit of phosphates occur in a large proportion of cases.

A French Method.

In search for improved methods I came first on a procedure used by French surgeons. A de Pezzer catheter of large size (say, 32 French) is introduced into the upper angle of the wound and the remainder carefully sewn up so as to allow of no leakage. A purse-string suture is placed around the tube to keep the bladder wall in constant apposition with it. The expanded end of the tube is drawn up so as to sit firmly against the mucous membrane around the margin of the bladder incision. Two fine catgut sutures, one above and one below the tube, hold the bladder up against the rectus muscle. In this way I found that I got a perfectly water-tight joint, not a drop of urine escaping into the wound, and that union per primam was invariable. Yet the method seemed to me to present three grave defects. In the first place, drainage was good enough in uncomplicated cases; yet wherever post-operative bleeding might occur, as for instance after prostatectomy, I could foresee grave risk of a clot obstructing the small eyes of the catheter, and a dangerous clot-retention occurring. In the second place, irrigation could only be performed by means of the tedious and meddlesome method of syphonage, which is intermittent, inefficient, and disturbs the patient, besides alternately distending and collapsing the bladder and so tending to produce leakage. Thirdly, it is the topmost point of the bladder which is drained.

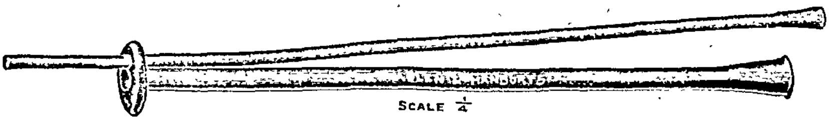


FIG. 1.—The bladder drainage and irrigation tube. Total length 16 inches, diameter nearly ½ inch. The flange appears more solid than it actually is, and its backward curve is better seen in Fig. 2.

Modification of the de Pezzer Method.

To obviate these three faults I have had a tube prepared for me by Messrs. Allen and Hanburys (Fig. 1). It is a de Pezzer catheter, in which the end has been altered into a flange as shown in Fig. 1. This flange is curved slightly backwards towards the tube, so that when drawn up into position in the bladder wound there is a degree of elastic tension which makes a secure joint. The size of the exit provided by this tube is sufficient to preclude any likelihood of a clot obstructing it. Vulcanised against the side of the larger tube is a smaller one, which passes through the flange; when in position, this projects into the bladder base, its external end is connected to a reservoir of lotion, through which constant irrigation of the bladder is effected, the flow leading into the bladder at its lowest point. There is thus a constant flow of fluid through the bladder, and no stagnation can occur in the bladder sump.

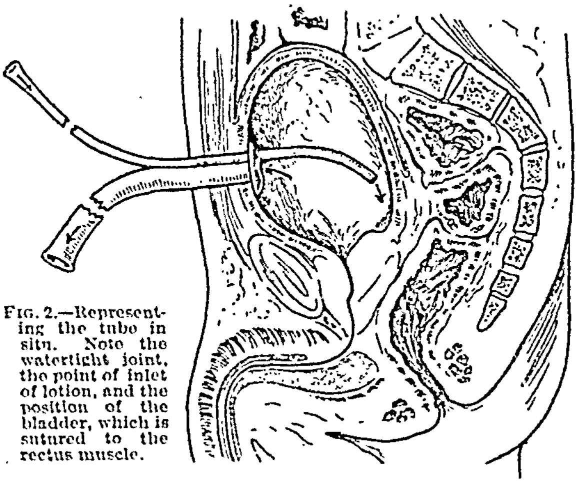

FIG. 2.—Representing the tube in situ. Note the watertight joint, the point of inlet of lotion, and the position of the bladder, which is sutured to the rectus muscle.

Details of Method.

By this method I have been successful in obtaining a perfectly dry wound in practically every case, the first dressing being allowed to remain in position until the tube is removed. I allow the tube to stay in for upwards of a week, considering that it is a valuable asset to have healing well advanced and the prevesical space firmly shut off before taking it out; after that the urine in drained into a Hamilton Irving suprapubic dish. Simple traction serves for the withdrawal of the tube, the intravesical flange crumpling up and passing through the wound without any difficulty. I do not know how long the bladder remains adherent to the abdominal wall, but certainly not for any long period. In all cases I have found that it functions perfectly when the suprapubic wound is healed. I have also proved that the upper wall of the bladder descends properly by observing it as it empties itself through an irrigating cystoscope.

In order to make sure that the bladder is not held in position for too long my stay sutures are of medium or fine ten-day catgut. Another, and perhaps a better, method is to use two sutures of silkworm-gut, which are passed right through the abdominal wall and support the bladder, pretty much in the same way as tension sutures are used to support the sheath of the rectus after a laparotomy; these are removed when the bladder-tube is withdrawn.

The tube should be placed in the upper angle of the bladder wound and should emerge about the middle of the skin incision. If it is placed too near the pubes there is a danger of adhesion occurring between the bladder wall and the os pubis, and formation of a fistula. An excellent reservoir for lotion is a thermos flask fitted with a Souttar's syphon, and suspended above the patient's bed. A flask of two quarts capacity can be obtained. The speed of the flow can be regulated by a cock on the syphon. It is a good plan to run the fluid alternately fast and slow, as when it is running fast it creates a disturbance in the bladder sump and cleanses it efficiently.

As regards the lotion to be used, I think that boric acid (sat. sol.) or oxy-cyanide of mercury (1–6000) is the most generally useful, but medication of the bladder can be applied with ease to suit varying circumstances; for instance, in the case of hæmorrhage, adrenalin or silver nitrate can be used; in the case of pain, phenacetin, novocaine, or stovain. It is generally well to keep the bladder fairly acid, and the addition of some acid sodium phosphate to the lotion can be recommended.

The temperature of the lotion in the thermos must be higher than that at which it is desired it should be when it reaches the bladder, as about 4° to 8° F. will be lost in passing down the tube according to the speed at which it is running. I find that patients experience comfort from this irrigation, especially if the lotion reaches the bladder at about 100° F. and when the flow is fairly quick.

I have treated this subject from the point of view of surgical cleanliness and the avoidance of leakage and of phosphatic deposit in the wound; but there is another aspect of the question which is probably of equal importance, and which I consider does not receive the attention which it deserves. A considerable proportion of cystotomy cases, especially among elderly prostatics, are on the verge of uræmia, which the operation accelerates or precipitates, not infrequently with a fatal issue. It seems to me reasonable to believe that a considerable share is played in this mortality by the absorption of toxic urinary bodies from the prevesical space. It is well known that if urine is injected into healthy rabbits a lethal dose is soon reached. How much more shall a dose prove lethal to a patient whose blood urea has already reached the danger zone, when urine is extravasated into the prevesical space—that excellent absorption area—especially when the effects of the operation are superadded? I hope to return to this subject. In the meantime I refer to it in order to emphasise the importance of a dry cystotomy wound.

JAS. B. MACALPINE, F.R.C.S.,
Honorary Surgeon and Surgeon-in-Charge of Genito-Urinary Department, Salford Royal Hospital, &c.

LITERARY INTELLIGENCE.—Messrs. Kegan Paul and Co. announce the decision to enlarge the scope of *The Psychic Research Quarterly* and to transform it into a general review of applied and general psychology under the title of *Psyche*. Education, psycho-analysis, industry, religion, social and personal relationships, psychical research, &c., will come within the scope of the new series, the first number of which will appear on July 15th.

FRENCH SUPPLEMENT TO THE LANCET

Under the Editorial Direction of
Professor CHARLES ACHARD, PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF PARIS.
AND
Dr. CHARLES FLANDIN, D.S.O., CHEF DE CLINIQUE A LA FACULTÉ DE PARIS.

METHODS OF HYSTERECTOMY.

BY E. DOUAY,
CHEF DES TRAVAUX, GYNÆCOLOGICAL DEPARTMENT, HÔPITAL BROCA (PROFESSOR J. L. FAURE).

WHEN the surgeon takes up his bistoury to perform abdominal hysterectomy for fibromyoma of the uterus or *salpingo-ovaritis he cannot know beforehand* what procedure he will adopt. If the cervix uteri is so affected that ablation appears to be necessary, he will perform total hysterectomy. The *cervix uteri* can usually be conserved, and its conservation holds more advantages than inconveniences. Subtotal hysterectomy is, in the opinion of J. L. Faure, the routine operation, established by 25 years of gynæcological surgery. Total hysterectomy remains an exceptional operation; in difficult cases it is advantageous first to perform the subtotal operation, and thus, when the *pelvis is largely emptied*, to remove the cervix, thus converting subtotal into total hysterectomy.

Only after the abdomen is opened, when the lesions are apparent, can the surgeon select his operation; his choice must be made in a few seconds of time and is of capital importance. It must be remembered that personal habit is to be considered; such and such a procedure, excellent *under some anatomical conditions*, becomes difficult and impracticable under others.

There are several guiding principles of use in assisting a judicious choice.

1. To discover the uterus amidst the lesions which obstruct the false pelvis, the first task is to separate the intestinal and epiploic adhesions and to disengage the fundus uteri; only when *this preparatory work is* finished can the attack on the utero-adnexal lesions be attacked.

2. To deal with the easier side first, leaving the more septic and more dangerous lesions until last.

3. Removal of the adherent adnexal mass must be done from the inner side and from below. Separation of adhesions at the lateral wall of the pelvis is a difficult and dangerous undertaking if begun from the *external side and carried out from above downwards.* It is made singularly easier if, after having found the inferior pole, of the ovaro-salpingitic mass, the operator works from below upwards.

4. When traction is applied to the uterus, that organ is only held in place by the cervix and its *connexions* with the vagina. *Once the cervix is divided, the uterus may be withdrawn*, and the pelvic cavity thus relieved. In difficult cases it is therefore well to perform section of the cervix as soon as possible during the operation.

To sum up—the surgeon should follow the shortest and least obstructed route to reach and perform section upon the cervix uteri in order to *deal with the lower* pole of the adnexal masses. As this shortest and least obstructed way is not always the same, different procedures are necessary according to circumstances. The whole art of the operator is to know how to adapt his method of attack to the lesions met with, and to employ the procedure most suited to the case in hand.

In easy cases all methods are suitable. H. A. Kelly's operation (Fig. 1), still described as the "American method," is one of those most used; the less affected side is first taken, and *after section of the cervix* the thick utero-adnexal mass is approached at its lower extremity and separated from below upwards. This is the method of choice for double salpingitis with a large unilateral adnexal mass. In fibromas without salpingitis, or with a slight form of salpingitis, Kelly's method is again preferable. As soon as possible after division of the cervix the uterus is drawn aside, leaving space to secure and cut the second uterine artery and easily to separate the adherent adnexa from below upwards.

Amongst operations suitable for easy cases, that of posterior decollation (J. L. Faure's method) (Fig. 2) is *particularly rapid.* In this procedure, the uterus is drawn forward and its posterior surface displayed; the *isthmic portion of the cervix is severed with curved* scissors from behind forwards. The *uterus is then* raised, the uterine arteries are cut, and the finger is inserted through the breach in the broad ligament to separate the corresponding adnexa. When inflamed adnexa are very adherent to the pelvic wall, but leave the edge of the uterus free, it is useful to perform *section of the broad ligament* between the adnexa and the uterus; this is Terrier's method—in such a case the most direct way of approach for division of the cervix. The uterus is first raised, and through the breach thus made the adnexal masses are successively dealt with.

In other cases, the adnexa on one side are found to *have adhesions in every direction,* whilst the other, less voluminous, adhere to the pelvic wall and prevent the use of Kelly's method, but leave between themselves and the uterus *sufficient space to admit of* performance of the first stage of Terrier's operation. (Fig. 3.) The *only available route to the cervix is then employed*; the latter is cut and the adnexa on that side raised, together with the uterus, to which they are adherent. This combined Kelly-Terrier's method of operation is concluded by simple ablation of the remaining adnexa.

Turning now to lesions still more pronounced—adnexal masses *on both sides, adherent to the pelvic wall* and to the uterus, so that it is impossible to pass round or behind them—what is to be done? Faure's method must be followed, and the incision made at the centre of the uterus, the operation of hysterectomy by uterine hemisection. (Fig. 4.) The fundus uteri being recognised and secured by two traction forceps, the uterine *cavity is laid open by an exactly median incision with* scissors, section being prolonged to the isthmus. The first half of the cervix is transversely divided, the uterine artery being secured and *the adnexa separated* according to routine; the other half of the uterus is *then removed in the same way.* For hemisection to be possible, the posterior face of the uterine body must be free or easily liberated. If this face be covered by the adnexal mass and unapproachable—an exceptional state of affairs—anterior decollation still remains to *the operator's hand. (Fig. 5.)*

It is very seldom that the vesico-uterine peritoneal cul-de-sac is not free; when free it permits sight of the isthmic portion of the cervix, which is cut by the scissors from before backwards, division being performed in sight. Division of the *cervix completed*, the way to the base of *the broad ligaments lies open*, and *after section of the uterine arteries* separation of the adnexal masses may be proceeded with.

In certain exceptionally difficult cases, the uterus is fixed in retroversion and retroflexion in the midst of the adherent masses. In order to disengage the organ, *anterior decollation (Fig. 6)* can be employed, and then hemisection (from below upwards) of the cervix already transversely divided towards the fundus uteri. By following round the uterine cavity the operator retains an excellent guide, permitting enlargement of

DIAGRAMS ILLUSTRATING VARIOUS METHODS OF HYSTERECTOMY.

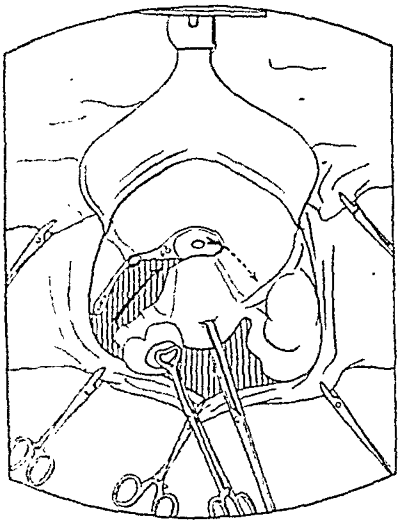

FIG. 1.—H. A. Kelly's method, admitting of approach, from behind and below, the most adherent form of adnexitis, thereby facilitating its decollation.

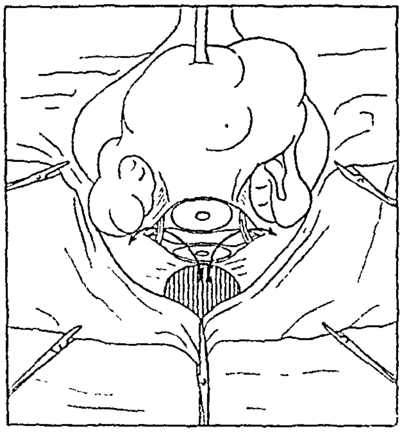

FIG. 2.—J. L. Faure's method of posterior decollation. When the cervix uteri is dissected the uterus can be removed and access gained to the adnexal mass.

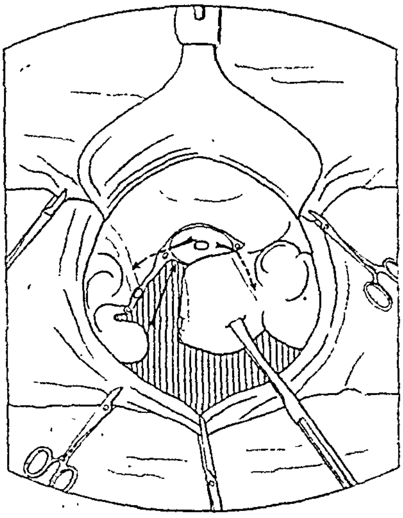

FIG. 3.—Combined Kelly-Terrier method. The cervix is reached through the space between the left adnexa and the uterus. After section it becomes possible to approach from below the right adnexa, presumably very adherent in all directions. The operation is terminated by separate removal of the left adnexa.

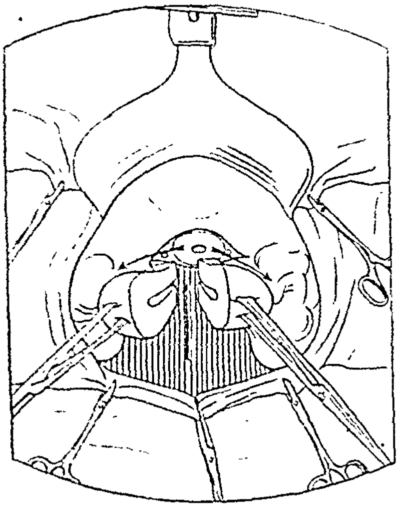

FIG. 4.—J. L. Faure's method of hemisection. As the adnexa completely fill the space between uterus and pelvic wall, median section of the uterus allows the cervix to be reached and dissected in order to approach the adnexa in turn.

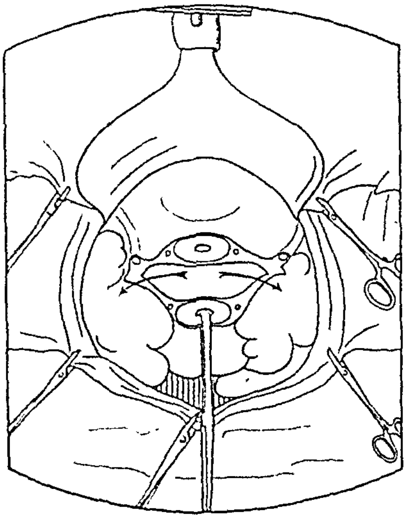

FIG. 5.—J. L. Faure's method of anterior decollation. As the uterus is in retroversion, the fundus being completely masked by adherent adnexal masses, the first section of the cervix permits recognition and compression of the uterine arteries, and then approach to the adnexa from below.

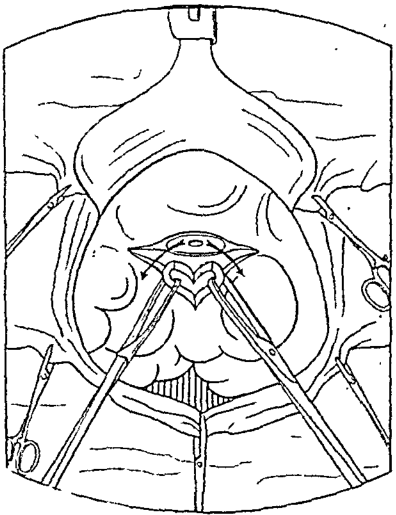

FIG. 6.—J. L. Faure's method of retrograde decollation and hemisection. After section of the cervix the uterus cannot be separated from the pouch of Douglas; hemisection, following the uterine cavity, is without danger and facilitates liberation of uterus and adnexa.

the route of approach without any risk. This method is described as anterior decollation with retrograde hemisection.

Lastly, there is the condition where the positions of lesions are supremely inconvenient for the operator—fibromyoma of the uterus, blocked in the pelvic cavity by a double salpingitis adherent in all directions. In this case, hemisection cannot be performed; anterior decollation is also impossible because the cervix uteri is not approachable *from in front*—between the fibroma and the bladder (crowded against the os pubis) there is not room to use the scissors. Évidement by morcellation must be performed, and as the fibromatous masses are removed, the pelvis will become less congested. The region of the cervix uteri is finally reached, and the operation is concluded as in hysterectomy by hemisection. This method of évidement is that of Professor P. Bégouin of Bordeaux.

SUBTOTAL HYSTERECTOMY:

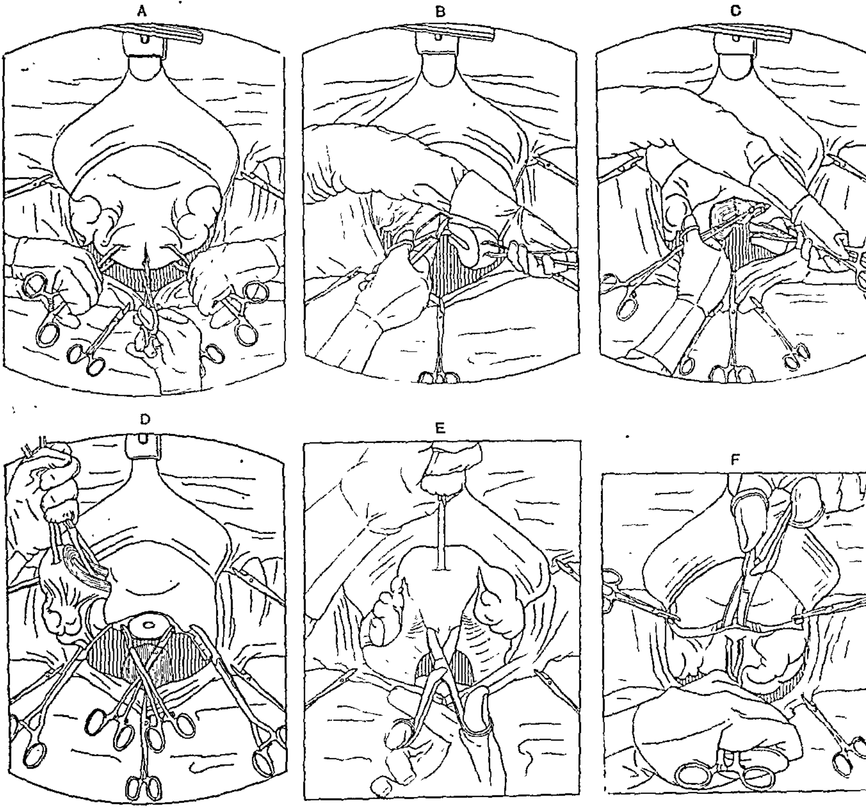
FAURE'S OPERATIONS OF HEMISECTION AND DECOLLATION.

BY E. DOUAY.

1. *Hysterectomy by Hemisection.*

HEMISECTION is the most remarkable of the less common operations of hysterectomy. It was performed for the first time by J. L. Faure in September, 1897, and is now practised throughout the world; there are even surgeons who wish to extend its indication to all cases of hysterectomy for double salpingitis, but it must remain an exceptional procedure, of considerable value in exceptional cases. The operation is indicated chiefly in bilateral salpingitis, with double adhesions to the pelvic wall on one side and to

DIAGRAMS ILLUSTRATING SIX STAGES IN THE OPERATION OF SUBTOTAL HYSTERECTOMY.



the uterus on the other. It is also indicated in certain adnexal tumours which fill the pelvis. Such cases are not rare; in salpingitis, for example, *they are found* in about one case out of every four. According to the statistics of the Hôpital Broca, hemisection has been performed in 24 per cent. of hysterectomies for salpingitis.

The procedure admits of following a method—sure, easy, and without danger—of section of the cervix uteri, ligature of the uterine arteries, and decollation of the adnexa. The uterine cavity is opened with the first cut and serves as a mark by which to continue median section to the isthmus; it is impossible to follow a false route, and division, if performed strictly in the median line, cannot involve any important artery (Fig. A). With regard to the possible disadvantages of opening the uterine cavity, danger of infection *by the uterine mucus is not usually to be feared.* Even in suppurating salpingitis, the uterine mucus is generally healthy and practically aseptic. In every case, however, it is well to thermocauterise the cavity as soon as the *latter is opened, on condition* that this cauterisation is done carefully and without hurry.

To perform hemisection, the necessary and sufficient condition is *to locate the fundus uteri*, which is not always easy amidst the adhesions which form obstructions in the pelvis. Two fixation forceps are *placed symmetrically on the fundus uteri, leaving the* middle of the organ free. The uterine cavity is then opened with scissors, and through the opening the large blade of the thermocautery is introduced several times, as far as the guard will allow *it to penetrate.* Median section is then prolonged to the isthmus.

The easier side—i.e., the side on which the adnexal lesions appear to be less extensive—is selected; *before attacking (transversely, with curved scissors)* one of the two halves of the cervix uteri, it is vitally necessary to grip the isthmus with traction forceps, as shown in Fig. B; this permits *balance from* outside, on the external side, of the hemi-uterus after section of the cervix, and also permits sight of the uterine artery, which must be compressed with *forceps* (Fig. C).

After section of the uterine artery, decollation of the adnexa begins; a finger is placed at the root of the broad ligament to separate the adnexum at its lower pole, *whilst traction applied to the uterus is transmitted* by the adhesions to the adnexal mass. It is sometimes useful to prolong the incision of the vesico-uterine peritoneum as far as the round ligament, as this facilitates separation of the anterior part of the adnexal mass-

The mass once freed, a clamp is fixed upon the utero-ovarian pedicle, division of which completes the first half of the operation. The other and more affected half is then proceeded with; the latter operation is performed more easily, since half of the pelvis is already freed (Fig. D).

2. *Hysterectomy by Decollation.*

J. L. Faure first performed this operation in 1900. In the same year, he gave an account of the technique and explained the different indications for each variety—posterior decollation for easy cases, anterior decollation for very difficult cases.

Posterior decollation.—If posterior decollation were to be reserved for easy cases, and considered as a rapid and dexterous procedure, it is probable that its technique would have fallen into disuse; but there are rare cases in which this method can be of great use beyond all question of technical skill—cases of fibroma of the uterine body with double salpingitis not involving the pouch of Douglas. The uterus and its fibroma are drawn towards the os pubis in order to disengage the posterior sac (Fig. E). Division of the cervix uteri, at the level of the isthmus, is carried out with one movement of powerful curved scissors. Section at this level does not endanger the bladder or the ureters. When the cervix is cut, the fibroma can be drawn away a few centimetres, thus disengaging the superior attachment. The uterine arteries are sometimes so close to the cervix that it is impossible to avoid dividing them at the same time, but it is easy immediately to compress them. Sometimes they lie more externally and remain intact on either side of the divided cervix. They are easily compressed and cut. Sometimes, however, they stretch and tear, and if bleeding they should immediately be secured; at other times, they are prevented from bleeding by having been stretched before tearing; in that case, their ligature can be left till the end of the operation.

Through the breach created by the separation of surfaces on division of the cervix, the finger can easily be introduced and the vesico-uterine peritoneum broken open. It then only remains to raise the adnexa and compress the utero-ovarian pedicle and the round ligament, section of which terminates the operation.

The total duration of this operation (including incision of the abdominal wall), as performed by Professor Faure, does not exceed from three to five minutes.

Anterior decollation.—This operation has not the same indications as posterior decollation, being reserved for very difficult cases, such as double adnexitis with many adhesions in all directions, and filling of Douglas's pouch. The posterior face of the uterus is not free, which hinders hemisection, but the vesico-uterine cul-de-sac is accessible after liberation of the epiploical or intestinal adhesions, if such liberation is necessary.

The cervix, being seen and found with the finger at the bottom of the cul-de-sac, is gripped transversely, at the level of the isthmus, with strong forceps; when thus rigidly fixed it is dissected transversely beneath the point where it is held, as shown in Fig. F. This dissection is made carefully by short cuts from in front backwards; during this procedure the cut edge of the cervical cavity is seen; the cutting is continued until the cervix is completely divided, but is not carried too far backwards for fear of involving the rectum, which, however, is generally separated from the cervix by the adnexal mass filling the pouch of Douglas.

The cervix uteri once dissected, the arteries appear on each side; if they are not seen, it is known where to look for them, this fact being one of the great advantages of the procedure. The ovaries having been cut, the finger may be admitted by the breach thus made in order to separate the posterior surface of the uterus and reach the adnexa by their bases. The operation may then be concluded without difficulty. It is advisable, after division of the cervix, to prolong the incision of the peritoneum on the sides as far as the round ligaments, which are compressed and cut. This procedure admits more readily of access to the adnexal masses.

ENDOWMENT OF MOTHERHOOD IN FRANCE.

(FROM AN OCCASIONAL CORRESPONDENT.)

THOSE Socialist Members of the French Parliament who refuse to follow the somewhat extensive movement in favour of Bolshevism are now specially concerned in schemes which they consider will promote the material welfare of the masses. They are urging extensions of the laws on compulsory insurance against sickness, accidents, old age, and we are even promised something that seems very like the endowment of motherhood. Indeed, child welfare with the population question holds a very large place in the public mind, for it is not only a public health but also a military problem.

No one has more pertinaciously insisted on the population problem than the former anti-nationalist, revolutionist, the creator of *La Guerre Sociale*, Gustave Hervé. He strove hard to persuade nations, but especially the French and the Germans, to meet a declaration of war by a general strike and to throw down their arms. When, however, he found that the Germans, in spite of their talk of internationalism, would fight to a man, Gustave Hervé changed the name of his paper to *La Victoire*, and urged that the first step towards assuring the peace of the world was to give the Germans a good sound thrashing. Having evolved thus far, he soon made the further discovery that, while the population of Germany increased rapidly and that of France remained stationary, Germany ultimately must predominate. Therefore every effort must be made to preserve the life and vitality of the existing population and to encourage its increase. Unfortunately, these efforts to increase the population have not yet met with any success. The first census returns just received show that there has been a decrease in the number of births in 10 out of 12 departments when compared with the census of 1911. Even where there has been an increase this is due to exceptional circumstances—for example, in the Alpes Maritimes, where so many strangers flock to the fashionable winter stations. But it is not only the birth-rate that has decreased; though the population was already almost stationary, the marriage-rate has not increased since the war in anything like the same ratio as in Germany. Thus the German press recently published statistics stating that the number of births in Berlin, which amounted to 40,832 in 1914, fell to 18,178 in 1917, but had risen again to 33,398 in 1920. Even more significant is the fact that the number of marriages had augmented from 38,919 in 1914 to 53,631 in 1920.

It is facts such as these that stimulate the patriotic Socialist to attack the rich dwellers of, for instance, the Champs-Elysées district of Paris, because they have much fewer children than the poor. Also for one child that dies in the Elysées quarter six children die at Ménilmontant. If the children of the poor cannot live it is because they have insufficient air, food, clothes, and warmth. Then l'Abbé Lemire, who represents in Parliament such Socialist tendencies as exist in the Roman Church, proposes the endowment of motherhood. Already the law of July 14th, 1913, grants public relief to numerous families, but the war has rendered necessary a wider measure; so l'Abbé Lemire recently proposed to the Chamber of Deputies that every mother of French nationality, belonging to the working classes, shall be entitled to receive Fr.360 *per annum* for each child under 16 years who is not working and earning wages. This will prevent children working too early, as well as lessening the burdens of parentage. The proposal was accepted by the Chamber. If French money had retained its normal value, this would be the same as if a law had been approved by the House of Commons endowing every workman's child with an income of £14 a year up to the age of 16. What the Senate has to say to the project has still to be seen. The fact, however, that such a measure has been widely approved in the Lower House is in itself a proof of the acute stage reached by the population problem. This is a large measure which should encourage early marriage among the wage-earners.

THE LANCET.

LONDON: SATURDAY, MAY 7, 1921.

Safe Conduct of Labour.

IN no department of our science and art has preventive medicine produced so small a result in recent years as in midwifery. While it is true that there has been in this country, what is not true for most other countries, some diminution in the percentage of deaths from puerperal sepsis, yet there has been hardly any diminution in the number of deaths from the accidents of childbirth. This is the more striking when we remember that nearly all these deaths in childbirth are due to preventable causes; and that the incidence of septic infection is extremely small in lying-in hospitals, while it is but little less in private practice at the present day than it was 20 or 30 years ago. The cause for this remarkable state of things has been pointed out by various writers, and is to be found mainly in the fact that in ordinary general practice the precautions taken against the occurrence of puerperal infection are largely inadequate, and the measures necessary for the prevention of the accidents of childbirth are often neglected. That cases of puerperal septicæmia of autogenous origin occur from time to time is due to conditions present in the patient's own body at confinement; yet in the great majority of cases the infection is introduced from without, in most instances by those attendant upon the patient.

It has been urged with great propriety that every case of labour should be regarded as of the nature of a surgical operation, and that precautions should be taken as if the patient were undergoing surgical procedure. This is the practice in lying-in hospitals, and the good results are to be seen in the almost complete immunity from puerperal infection that patients confined in these institutions enjoy. At the present day, unhappily, the voice of the obstetrician teaching the doctrine of midwifery as a surgical art "is that of one preaching in the wilderness"; and although most would concede the justice of the argument, few are prepared to carry it to its logical conclusion, and to treat their lying-in cases as they do their patients who are to undergo some surgical operation. Certainly surgical cleansing of the vulva is a difficult procedure, and in ordinary conditions the external genitalia swarm with organisms possessing pathogenic properties. We must admit, further, that most cases of infection owe their origin to the introduction of such organisms into the genital tract as a result of the manipulations carried out in conducting the case, and in many instances infection takes place during vaginal examinations. The danger is naturally increased the more frequently vaginal examinations are made. There is a story current of a well-known obstetric teacher who used to tell his students the best thing a young practitioner could do when called to a case of labour was "to leave his midwifery bag at home and to keep his hands in his pockets," and in this dogmatic assertion there is more than a spice of truth. It would be no exaggeration to say that meddlesome midwifery kills as many patients as it saves. It is appalling to remember that in these days over 3000 women die every year in England and Wales as a result of pregnancy and childbirth, and that the great majority of these deaths are due to preventable causes. Besides this, we must remember that the morbidity of childbirth in private practice amounts to something like 15–20 per cent. of all cases, and that many of these women suffer in after-life from various disabilities due to the mild grades of infection comprised under this term. The prevention of septic infection in childbed can be effected in one of two ways: either by the recognition of the principle that childbirth is really analogous to a surgical operation and requires just as much care to avoid infection, or by not practising those manœuvres which are likely to lead to infection—namely, vaginal examinations or unnecessary interference with the normal course of labour.

The acquisition of a right judgment in deciding whether or no to interfere is mainly dependent upon the proper teaching of the student. The avoidance of vaginal examinations is a simpler matter and more readily attained. Abdominal palpation, combined if necessary with rectal examination, will give practically all the information that can be obtained by vaginal examination, and these two methods have the great merit that they entail no risk of infection. Abdominal palpation is the more important of the two, and sufficient information can be obtained by this method of examination for the safe conduct of the great majority of cases of labour. It requires only the necessary perseverance on the part of the student to familiarise himself with the procedure. By abdominal palpation everything can be determined in an ordinary case of labour except the degree of dilatation of the cervical canal and the presence or absence of prolapse of the cord, and the diagnosis of either of these two conditions can readily be made through the rectum. It should be considered gross neglect on the part of a practitioner, who undertakes to attend a woman in her confinement, if he does not carry out a careful examination of the abdomen four to six weeks before full term, combined in a primipara with a careful pelvimetry, and in all cases with the examination of the urine. The proper teaching of ante-partum examination of the patient is just as important, and in many ways more important, than the proper teaching of the conduct of a labour, and has the great value that the instructed practitioner in many cases may foresee and avoid accidents and complications which would otherwise occur. In our view every student should be well grounded in the proper methods of practising abdominal palpation in cases of pregnancy, and we would lay great stress upon the importance of teaching the use of rectal examinations during labour and the avoidance as far as possible of all intra-vaginal manipulations. The increased impetus which has been given lately to the setting up of ante-natal clinics will, we hope, have some influence in this direction, but much remains to be done, as we think that the importance of conducting cases of labour without any vaginal examinations at all, a procedure which in most cases it is quite easy to carry out, is not sufficiently emphasised by teachers of midwifery either to students or to midwives.

Industrial Morbidity.

THE Society of Industrial Engineers, which held its Spring Convention at Milwaukee last week, discussed Industrial Leadership, the note of the discussion being that men and women do not work for wages alone, nor are elaborate welfare organisations, lunch-rooms, and bonus plans per se sufficient to call forth the best that is in them. The genius of such men as WATT and ARKWRIGHT made Great Britain birth-place of that modern industrialism which has transformed civilised life; with us also a hundred years later, owing to the initiative of FARR and SIMON, public health medicine first saw light. But the close application of public health medicine to industrial life waits yet to be effected. When it is, we may hope for the dawn of greater contentment in the industrial world. Already there are signs, even though as yet no larger than a man's hand, appearing across the sea. Other nations before have copied and often improved upon what we have started. Many writers in this country, especially since the comprehensive reports of GREENHOW 70 years ago, have drawn attention to the effect of industry upon health. For the most part appeal in proof has been made to mortality data, often scanty and imperfect; evidence based on morbidity, which provides more plentiful material, is needed, but has not been forthcoming. While we are waiting the United States are moving, and during the last 18 months, in their public health reports,[1] there have appeared no less than eight publications dealing with the subject. A committee reported upon the need for investigation and upon a standard method of classification of sickness; that adopted is based on the International List of Causes of Death. Next the Public Health Service offered to devise standard forms and analyse in its statistical office records submitted. Then followed the analysis of records for 1919 of a manufacturing company employing 6700 workers. In December, 1920, there appeared an analysis of sickness frequency among industrial employees for the first half of that year, based on figures supplied by sick benefit associations which are coöperating with the Public Health Service. Then came a paper dealing with the diseases among steel workers studied by investigating the records during a two-year period ending May 31st, 1920, of a large employees' sick benefit association. In March of this year the analysis of sickness frequency for 1920 is carried forward for a further three months. Only cases of sickness incapacitating from work for seven days or more are included.

The occurrence of epidemics of influenza abnormally swells the total amount of sickness experienced, but, omitting this unusual feature, certain interesting facts emerge. Among the steel workers at the head of the order of frequency were 313 cases of bronchitis, 212 of rheumatism, 164 of pneumonia, 121 of rupture, 98 of gastritis, 95 of appendicitis, and 92 of infected injuries, after which no one cause provided more than 75 cases. The general frequency of sickness, based upon information received from 27 reporting associations, is stated month by month as the number of cases per 1000 persons per year; here again, respiratory diseases (including influenza) lead with 243 cases in February, falling to 10 in July; digestive troubles come second with 24 in January and March, falling to 14 in September, general diseases accounted for 18 in January and 7 in September, and nervous diseases for 8·5 in February and 4 in July and August. "When it is considered," to quote the Public Health Reports, "that cases incapacitating for less than one week are not included, the frequency rates seem surprisingly high. Even in September, the month of lowest incidence in the months under review, the annual case rate was 56 per 1000—in February it was 326. This is true in spite of the fact that the members of a large proportion of the associations are selected workers." The almost entire absence of industrial poisonings as a cause of disability is noted. Clearly they do not bulk largely in the field of industrial medicine. Great differences are reported in the case incidence in different associations. "In February the frequency for Association A was 118 per 1000, while for Association B it was 585 per 1000. In July the rate for Association S was 191 per 1000, while Association R in the same city, and having about the same number of members (approximately 1150 in either association), reported only one case occurring in July, making the rate only 10 cases per 1000 per year." The reason of these wide variations awaits further data and information.

We see here the foundations being laid for the science of industrial medicine, a science which cannot fail to throw light on the influences which reduce vitality. We take the opportunity of calling attention now to a conference of medical men associated with industry which is being called on June 2nd by the Industrial Welfare Society.[2] It is intended at this conference to coördinate the individual efforts made by firms in different parts of the country to deal with their own peculiar medical difficulties. This is work which we recommend to the attention of the reconstructed Industrial Fatigue Research Board; no work is more needed, and in no way can they better prove the wisdom of those who have maintained their activities and widened their scope.

◆

Pruritus Ani.

Pruritus ani, as a distressing and persistent symptom with a varied and often obscure origin, has always been a stumbling-block to the practitioner and a fruitful source of revenue to the vendor of patent ointments. The recent discussion held by the Subsection of Proctology of the Royal Society of Medicine[3] should help to place the pathology of this nerve-racking complaint on a firmer basis. There was general agreement with Mr. J. P. LOCKHART-MUMMERY, who opened the discussion, that in the great majority of cases the irritation is due to a chronic infective dermatitis, and that lesions of the anal canal producing a chronic discharge are the main factors in causation. Warmth, moisture, and organisms held up in puckered folds of skin, with inadequate attention to cleanliness, seem to be the essential factors in a chronic infection of a cutaneous area richly supplied with nerve-endings, a condition which is kept up and aggravated by persistent scratching. It is a noticeable fact in support of this contention that pruritus is far more common among hospital patients than in the well-to-do.

[1] Public Health Reports, Government Printing Office, Washington, August 30th, 1918; Oct. 17th, 1919; April 9th, 1920; Sept. 10th, 1920; Nov. 19th, 1920; Dec. 3rd, 1920; Dec. 31st, 1920; March 4th, 1921.

[2] We are asked by the director of this Society, Rev. Robert R. Hyde, to state that he will be glad to hear from any doctors who are definitely and primarily concerned with the medical affairs of industry. The offices of the Industrial Welfare Society are at 51, Palace-street, Westminster, London, S.W. 1.

[3] THE LANCET, April 23rd, p. 859.

Although in the majority of cases some lesion of the anal canal will be found, in others a weak sphincter or slight prolapse of the mucosa will explain the discharge. Sir CHARLES GORDON-WATSON called attention to the frequency with which hypertrophy of the anal papillæ, the sense-organs of the rectum, is met with in cases of pruritus, and mentioned that over a period of 18 months in the out-patient department of St. Mark's Hospital he found hypertrophy of the papillæ, with or without other lesions, in 53 out of 86 cases suffering from pruritus. The significance of these observations was confirmed by the excellent results which followed cauterisation of these papillæ. He pointed out that many cases of supposed functional pruritus, with little or no visible dermatitis, can be cured by cauterisation of the papillæ when these are obviously hypertrophied. And in this view Mr. ERNEST MILES, the President of the Section, concurred, attributing papillary hypertrophy to constipation. Evidently the rôle of Morgagni's papillæ has not received the attention it merits. It may be regretted that no pathologist came forward in this discussion to confirm or confute the work of Dr. DWIGHT MURRAY in America, who has made out a strong case for the *Streptococcus fæcalis* as the important agent in the skin infection, and who advocates vaccine therapy. Vaccine therapy for pruritus has not found much favour in this country; it may not have received an adequate trial. Research in this direction is needed. Treatment directed to the cure of the rectal complaint leads to a speedy cure of the dermatitis in the early stages, when the latter is treated on aseptic lines with special attention to dryness and the use of non-greasy preparations. If the dermatitis is of long standing, and if the skin has lost its elasticity and has become fibrous and friable, the difficulties of effecting a cure become greatly increased, so that resort to ionisation, high-frequency current, X rays and radium, are often necessary. Opinions vary as to the permanent value of X-rays, and a note of warning was sounded at the discussion as to the dangers of an overdose in this region with the appalling condition of skin that may result. Dr. N. S. FINZI was of opinion that, on the whole, radium was of more permanent value than X rays in obstinate cases and he spoke well of high-frequency.

In the last resort surgeons at present favour the operation, devised by the late Sir CHARLES BALL (1851–1916), of dissecting up the perianal skin so as completely to divide all the nerve-endings in this region. In doing so it is important to undercut the lining of the anal canal as well as the perianal skin. The test of an adequate operation is complete anal anæsthesia after operation, with return of sensation within about six weeks. Success without recurrence has been claimed for the great majority of such operations; other surgeons are less confident of permanent cure. It is generally agreed that when pathological lesions of the anal canal, general diseases such as glycosuria, and intestinal parasites, especially the oxyuris, in adults as well as children, have been excluded, there remains a small residue with no definable cause. For the most part these cases occur among neuropaths and must be regarded as neurotic rather than neuritic. As Mr. MILES put it in his concluding remarks, they remain to remind us that there is a limit to medicine and surgery. Future research should be directed towards removing this limitation.

Annotations.

"Ne quid nimis."

THE SEVEREST ANÆMIAS.

THAT changes may occur in the circulating blood of workers with X rays and radium has been recognised for some time, and a case of fatal anæmia in a practitioner of this branch of medicine was recently reported in THE LANCET. Now that the danger is realised there is no doubt that adequate measures will be taken to meet it, for no one would be willing to relinquish so powerful a therapeutic weapon. Further, it is apparent that a fresh means has become available for the experimental study of the obscure conditions grouped together under the name of the severest anæmias. Nowadays the conception of a primary idiopathic pernicious anæmia is no longer held. Certain cases of severe or fatal anæmia are idiopathic in the sense that their ætiology remains unknown, but it is generally recognised that the term *pernicious anæmia* includes a variety of conditions which are alike in that their chief symptoms are diminution in the number of red blood cells, associated with a relative increase in amount of hæmoglobin and a leucopenia. It is still uncertain, however, how this condition is brought about, whether it is due to destruction of the red blood cells, or whether the fault lies in the hæmopoietic organs. The invariable presence of large quantities of iron in the organs of patients dying from pernicious anæmia suggests that an abnormal destruction of erythrocytes is an important factor in the production of the anæmia, but it is not a proof of the presence of a hæmolytic toxin; it may merely mean that unhealthy cells are produced by the bone marrow. The presence of megaloblasts in the blood stream in pernicious anæmia points to a pathological condition of the marrow, for the small normoblasts rather than the large nucleated forms are characteristic of normal regeneration, and the neutrophile leucopenia so commonly seen in this disease is further indication that the hæmopoietic system is at fault. Throughout life the cells of the blood, in common with almost all the other cells of the body, are constantly dying and being replaced, and the hæmopoietic tissues possess such remarkable powers of compensation that a considerable destruction or loss of blood is possible without there being more than a transient anæmia. Nevertheless it is conceivable that a perfectly healthy bone marrow may be unable to cope with the calls made upon it by abnormal, continued blood destruction, with the result that a recognisable anæmia occurs. More commonly, however, the deleterious agent which destroys the cells of the circulating blood acts also upon the marrow, so that there is both abnormal destruction and defective regeneration. An interesting possibility is the failure of the marrow to make any new cells at all, when the erythrocytes would disappear from the circulation at the end of their ten days or so of life, and the resulting anæmia would be sudden and absolute. Such a primary aplastic anæmia is a purely hypothetical condition, but what might be called secondary aplastic anæmias, in which the marrow gradually ceases to respond to the stimulus to make new cells, undoubtedly do occur. In life these cases can be diagnosed with some degree of certainty by the severe and increasing anæmia, with the complete absence of any signs of regeneration in the red cells of the circulating blood and the extreme leucopenia affecting chiefly the granular leucocytes. But an absolute diagnosis can only be made from an examination of the bone marrow when it is found that the hæmoblastic reaction is absent. The shafts of the long bones contain nothing but fat instead of red marrow, as is usual in pernicious anæmia, and the red marrow itself is atrophic. Whether an anæmia is ever aplastic from the beginning remains to be proved. Usually the condition can be regarded as the stage of exhaustion in the course of a particular disease, but the rapidly fatal termination of certain cases certainly suggests a primary lesion in the marrow. It is possible that radium and X rays may act thus, and it may be confidently expected that further research will do much to elucidate this obscure condition. Light may come from unexpected directions, and we commend to the attention of our readers the curious similarity of effect produced by absence of vitamins and by exposure to X rays and radium, which is the subject of an important communication this week in our original columns.

NATURAL HEALTH CENTRES.

THE death of Dr. Theodor Schott, which recently occurred at Frankfurt, removes one who had for 44 years exactly applied a number of physical agents to the treatment of chronic disease of the heart, and in whose lifetime the Nauheim method became well known all over the world. A paper which we published last week contained an exact record by four competent observers at one of our own spas of the experimental basis claimed for certain popular methods of electrical treatment. The move towards precision in the study of physical therapeutics is very welcome. The new impetus given to the study of incipient and chronic disease has naturally directed fresh attention to the great sources of energy and healing in waters and climates. An interesting symposium by French authorities appears in the *Vie Médicale* for April 8th. Attention is there called to the "gamut" of French marine climates, of the Channel, Ocean, and Mediterranean coasts, and to the varied Alpine locations, which are available—but far too little utilised—for the treatment of tuberculosis, both in children and adults. Tuberculous maladies form but one group of many chronic infective and toxic conditions that are amenable to climatic influences. We are also reminded of the numerous natural waters of France, many of them situated in fine, sub-Alpine climates, where arthritic affections and dermatoses, cardio-vascular affections, and disorders of digestion, of metabolism, and of the nerve centres, can be treated by waters and baths in beautiful and stimulating surroundings. Dr. H. Jumon, in a study of La Bourboule, states very truly that all such "cures" are in themselves unavoidably fatiguing and ought to be carried out in an atmosphere of peace and repose. He deplores the tendency for health resorts to become merely centres of excitement for pleasure-seekers. This is a very old tendency, and has in the past spoiled many a famous spa. Pleasant distraction, amusement, music are, of course, wanted by the health-seeker, together with the magic of change in daily surroundings, habits, and thoughts. But these should form only the setting for a definite organised medical specialty. The health resort is a treatment centre for incipient and chronic disease. Its accidental and obvious features as a place of recreation and pleasure should not be allowed to obscure its essential purpose of healing and fortification against disease. Moreover, as we have hinted, there is now a body of exact knowledge drawn from many countries and times, dealing with the effective utilisation of health resorts by invalids. It forms no part of authorised medical teaching, or only in an occasional and sporadic way. Sometimes, in the laudable search for definition, health stations are labelled too precisely, as in France. For example, obesity is referred to Brides-les-Bains and enteritis to Châtel-Guyon. We ought to look a little deeper. Symptomatic maladies arise from many causes, and it would be more useful for the medical man to direct his patients according to underlying constitutional conditions, which respond in a definite manner to different forms of hydrological treatment. This hiatus in the education of the practitioner should be filled by instruction in the general principles upon which incipient systemic disorders are actually amenable to the methods of physical medicine. At present the lack of this knowledge is a fruitful source of unfounded pretensions and empirical practice. As one of our French colleagues observes, doctors are apt to refer their patients to waters and baths with a veiled scepticism, and often in order to get rid of them for a time, or simply to give them pleasure.

Dr. G. Bardet, director of the Laboratory of Hydrology in Paris, points out in the same journal the great opportunity existing at the present time for able young practitioners to specialise in climatic and hydrological medicine. Such a movement has already taken firm hold in Switzerland, Belgium, Holland, Italy, and Germany. The creation of new stations, both in the Alps and along the coasts of France, with adequate medical organisation would be, he thinks, of immense benefit to his country. The young physician, specialising according to the local indications during the summer, could spend the winter to great advantage in study and travel. He estimates that from 500 to 600 such medical men could thus find scope for practice as well as study in medical posts of this kind. Certainly it is hardly open to doubt that a more complete provision of health stations is needed, whether for the tuberculous, for delicate children, for the unfit in all walks of life, or for the overworked and the elderly. In England the coast climates—perhaps even more remarkably than in France—offer a complete range of sedative and tonic influences. Inland we have moors and hills, and what these lose in altitude they gain in the tonic influence of northern latitude. But here again we are driven back to the need for more knowledge and coördination. We are glad to learn that an International Society of Medical Hydrology is to devote itself to throwing light on these problems.

ADVISORY COMMITTEE ON THE WELFARE OF THE BLIND.

IN view of the passing of the Blind Persons Act, 1920, the Minister of Health has reconstituted the Advisory Committee on the Welfare of the Blind, so as to afford representation to the local authorities under the Act and to voluntary agencies for the blind, and the following have been appointed members of the Committee: Right Hon. G. H. Roberts, M.P. (Chairman), Mr. P. M. Evans, LL.D. (Vice-Chairman), Mr. Alderman F. Askew, Mr. A. M. Bernard, Miss Winifred Bramhall, Sir Coles Child, Bart., Mr. H. Davey, Mr. James Graham, Mr. Councillor J. A. Hill, Sir William Hodgson, Mr. T. Holt, Mr. A. L. Lowe, C.B.E., Mr. G. F. Mowatt, Mr. H. J. Munro, Sir Arthur Pearson, Bart., C.B.E., Mrs. Wilton Phipps, Rev. P. S. G. Propert, Mr. R. Richardson, M.P., Mr. W. H. Tate. The Committee will advise the Minister on matters relating to the care and supervision of the blind, including any question that may be specially referred to them by the Minister. Mr. F. M. Chapman, of the Ministry of Health, will act as Secretary.

OXYGEN INSUFFLATION IN MORPHINE POISONING.

Professor Brauer has recently discussed[1] the treatment of morphine poisoning as lately adopted at the Eppendorfer Hospital in all severe cases. In his opinion morphine poisoning proves fatal chiefly on account of the CO_2 intoxication which it induces; if this can be prevented the most dangerous symptoms of morphine poisoning are warded off, and doses of morphine which would otherwise inevitably prove fatal can be tolerated with comparative impunity. In his first case, treated by insufflation of oxygen, this procedure was more or less a counsel of despair, for all the standard methods of treatment had been tried for many hours, and life was slowly ebbing away. Yet, within five minutes of flushing the trachea with oxygen there was a remarkable improvement in the patient's colouring, which had been cyanosed. She soon began to breathe automatically, and it was evident that in a few minutes a change had been effected, converting a hopeless case into one with every prospect of recovery. The insufflation of oxygen was continued for about 12 hours, and though aspiration pneumonia of both lower lobes developed, the patient ultimately recovered. The procedure recommended by Professor Brauer is described in considerable detail. Tracheotomy having been performed, a long, soft rubber catheter, fitting quite loosely in the tracheotomy tube, is attached to an oxygen cylinder. An air filter is interposed as well as a contrivance for keeping the oxygen moist when the insufflation has to be continued for a long time. The supply of oxygen is graduated by bubbling it through an antiseptic solution before the catheter is introduced into the trachea. When the end of the catheter reaches the bifurcation of the trachea or one of the bronchi it provokes coughing, and thus helps to clear the respiratory passages and facilitate respiration. As long as the escape of oxygen is not too rapid the lungs cannot be over-distended, for gases can easily escape between the cather and the loosely fitting tracheotomy tube, as well as by the larynx. An additional advantage of this procedure is the opportunity it affords for the escape of CO_2, which is otherwise apt to collect in the upper respiratory passages. It is interesting to note that Professor Brauer is so doubtful as to the value of atropine in morphine poisoning that he does not prescribe it in severe cases. His attitude towards this remedy is much the same as that voiced by Professor Cushny in the 1905 edition of his "Text-book of Pharmacology," in which he refers to the "long and weary dispute as to the value of atropine."

THE TREND OF FOOD PRICES.

THE *Economic Review* for April 22nd prints a table of great value, comparing the retail price of food in many countries during the last seven years, taking the year 1914 as the basis. The month of July has been chosen for the comparison, the figures are the official index numbers taken from the *International Labour Review*, and we reproduce them substantially, omitting a few exceptions and qualifications which hardly affect their comparative value.

Date.	United Kingdom.	Canada.	Australia.	New Zealand.	South Africa.	U.S.A.	Paris.	Belgium.	Amsterdam.	Switzerland.	Rome.	Milan.	Spain.	Denmark.	Norway.	Sweden.	Calcutta.

Man does not live by bread alone, and in the Dominions personal apparel has long been relatively more costly than at home. But when it comes to the pinch it is the actual cost of essential foodstuffs as purchased that determines economic stress, and the table is instructive in this regard.

STAB WOUND OF BOTH VENTRICLES: RECOVERY.

IN his Bradshaw lecture[1] on the Surgery of the Heart, on Dec. 11th, 1919, Sir Charles Ballance tabulated 152 cases of operations on the pericardium and heart performed for injuries. No wound of both ventricles was mentioned by him, but two cases of double wound of right ventricle and auricle and of right ventricle alone were cited, both fatal. Dr. E. M. Freese has recently reported[2] the following remarkable case of recovery after a stab wound of both ventricles. A coloured man was stabbed at 8 P.M., and brought to hospital at 8.30 unconscious. Respirations were feeble and shallow, and no pulse was perceptible in radial or carotid arteries. The pupils were widely dilated and the skin was bathed in cold perspiration. A spot of blood on the shirt over the heart indicated the site of the wound, which was 1½ in. long, and in the fourth interspace 2 in. to the left of the sternum. Only a small amount of blood had escaped, not enough to account for the state of the patient. The area of cardiac dullness was much increased. The diagnosis of wound of the heart with hæmorrhage into the pericardium seemed evident. There was no hæmoptysis. The chest was painted with tincture of iodine, and under light ether anæsthesia, with the wound as the centre, a U-shaped incision was made with the base outwards. The skin and pectoral muscles were turned back, the fourth and fifth costal cartilages were cut through, and the corresponding ribs carefully separated from the pleura for about three inches, and then divided with bone forceps and turned outwards. This gave a very satisfactory exposure, and the wound in the pericardium, from which there was a small stream of blood, was at once seen. The wound was enlarged upwards and to the right. The lack of even carotid pulse was now explained by the pericardium being packed with clot. When this was scooped out the heart at once began to beat violently, spurting blood on to the anæsthetist. The heart wound was instantly plugged with the tip of the left index finger until a suture was passed and tied. This nearly checked the flow, but it was necessary to use a second suture. Much blood was lost during these manipulations, but the action of the heart was fair and the anæsthetist could feel the pulse. But it was now found that blood was welling up behind the heart. Grasping the heart in the left hand, with index finger hooked round the apex, Dr. Freese raised the organ so as to expose a wound in the posterior wall nearly as large as the one closed in the anterior. Owing to the thickness of the left ventricle the wound was not bleeding so rapidly. It was closed with two sutures. The heart had almost stopped beating and no pulse could be felt. An intravenous injection of saline solution was given, the pericardium was sponged out and closed by continuous suture, the ribs were replaced, and the musculocutaneous flap was sutured in place without drainage. The patient was taken to his room, where he arrived at 9.15; the foot of the bed was elevated, hot-water bottles were placed around him, a hypodermic injection of morphine and atropine was given, and rectal infusion was started. On reaching his room the pulse was 72, but very small. The after-history was satisfactory; at no time was there cause for alarm. Bronchitis developed on the second day and was annoying on account of painful cough, which was controlled with heroin. On the fourth day a loud friction murmur was heard over the heart (pericarditis). This lasted for two weeks, but there was never any sign of fluid sufficient to demand interference. The highest temperature, 102°F., was reached on the third day, with a pulse of 150. At this time the bronchitis was most severe. The temperature rose every afternoon to 100° until the eighteenth day. He was discharged a month after operation. The wound had long since healed, and there were no physical signs. X ray examination showed only some thickening of the pleura, with perhaps a little enlargement of the heart shadow.

SPLENOMEGALY.

IN their review of recent work on diseases of the spleen in the May number of *Medical Science*, Dr. Gordon Ward and Dr. J. D. Rolleston devote several pages to a consideration of various forms of splenomegaly which have been lately described by British, French, German, Italian, and American observers. Not the least interesting of them is the form to which Luccarrelli has given the provisional title of "war splenomegaly," having found it in a considerable number of soldiers without being able to connect it with any present or past disease such as malaria, enteric fever, spirochætosis ictero-hæmorrhagica, or trench fever. Among the various explanations which have been offered to account for the condition are, first, that it is a toxic state of intestinal origin due to the food and character of life at the front, including mental and emotional factors; secondly, that it is an abortive form of trench fever; and, thirdly, that it is due to the presence of the *Spirochæta icterohæmorrhagiæ* or some other organism. This form of splenomegaly is apparently quite distinct from the obscure and rare disease described by Sir John Rose Bradford[1] in his Lumleian lectures on his experiences during the campaign in France and Flanders in 1914–19. The clinical picture in his cases was that of a febrile illness closely resembling enteric fever and lasting several weeks, during which the spleen slowly increased in size to that reached in ordinary splenomedullary leukæmia. The blood examination showed a condition similar to that of splenic anæmia, a diminution of the red cells and a considerable leucopenia. Repeated examination of the blood and stools failed to show any organism of the enteric group, and the Widal reaction was uniformly negative. Another rare form of splenomegaly is that described by Weil, in which the Wassermann reaction was positive though there was no evidence of syphilis, inherited or acquired. Antisyphilitic treatment in these cases had no effect on the splenomegaly or the Wassermann reaction, but caused an aggravation of the general condition. Lastly, reference should be made to the cases reported by Lévy-Franckel of splenomegaly following injections of neosalvarsan for non-syphilitic skin conditions and apparently due to this drug, as all other causes such as syphilis, leukæmia, pseudo-leukæmia, tuberculosis, and cancer could be excluded.

PULMONARY TUBERCULOSIS AND LIFE ASSURANCE.

IN a recently published statistical Bulletin of the Metropolitan Life Insurance Company, U.S.A., we meet with the following startling declaration :—

> "More money was disbursed on account of tuberculosis than for any other disease. Despite the fact that the death-rate for tuberculous diseases in 1920 was the lowest in the history of the company, and was two-fifths below that of 1911, more than six and one-half millions were paid for death claims resulting from tuberculosis."

Tuberculosis in this connexion is practically synonymous with pulmonary tuberculosis. *Every company* has the same experience. In the medico-actuarial mortality investigation compiled by the Association of Life Insurance Medical Directors and the Actuarial Society of America, the following percentages of deaths from pulmonary tuberculosis to total deaths among standard lives are given. Between the ages of 15 and 29, males 22·5 per cent., females 27·2 per cent.; between 30 and 44, males 12·3 per cent., females 13·9 per cent.; from the age of 45 and over, males 4·5 per cent., females 4 per cent. It is clear, therefore, that by *far* the greatest mortality is experienced among the younger lives, and that it is with these that the greatest loss occurs. Many of the claims fall in the earlier years of life insurance, and, as we *pointed* out recently, the majority of early claims are due to pulmonary tuberculosis. That a high mortality from this disease should occur is unavoidable at present, but it is felt that with better education of the medical profession generally in this subject many of the early claims—those, let us say, in the first year of insurance—could be avoided. It cannot be too widely known that certain factors definitely predispose to tuberculosis, if they are not indicative of an actual tuberculous state. They are: a family history of the disease, a tall height with relatively low weight; a *past history of pleurisy*. Young, tall underweights are extremely risky lives from this point of view. The significance of pleurisy is not as widely recognised as it should be; it is not going too far to say that pleurisy, when not due to some known cause such as pneumonia, is, in the majority of cases, definitely tuberculous. Another stumbling-block is that many practitioners are content with such diagnoses as unilateral bronchitis, unexplained and unclassified "anæmia," or "repeated influenzal attacks." Under such subterfuges of ignorance, pulmonary tuberculosis not infrequently masquerades. Putting aside all intricate or subtle methods of detection of early phthisis, there are four cardinal signs and symptoms, the conjunction of any two or three of which is an omen so sinister that the strongest suspicion should be aroused, and examinations of the sputum made for tubercle bacilli, repeated many times if necessary; there are progressive loss of weight, progressive weakness, hæmoptysis (though ever so slight), and evening fever. Simple as these things are, their general recognition would result in earlier diagnosis of this dread disease, a far greater percentage of recoveries, a great saving of the public money now spent on institutions and hospitals, and a sparing of immense losses generally in the financial affairs of the country. The early claim for pulmonary tuberculosis blesses neither him who gives nor he who takes, and is, we fear, often a slur on the skill of our profession.

HOSPITALS AND INCOME-TAX.

LAST November a subcommittee was appointed by King Edward's Hospital Fund for London to consider the question of securing exemption from income-tax on voluntary contributions to hospitals. Sir Walter Trower, Sir Basil Mayhew, Mr. Henry L. Hopkinson, and Mr. John G. Griffiths were the members of this committee, the first-named being elected as its chairman. The report which has just been issued, signed by three members, records the opinion that relief in respect of income-tax paid on subscriptions and donations to hospitals is practicable, and offers a definite form of financial aid to embarrassed hospital finance. They desire that their report should be laid before Lord Cave's Hospital Committee. Sir Walter Trower adds a note regretting that he is unable to accept the principle of exemption from income-tax, which he finds to be inconsistent with the report of the Royal Commission on the Income-tax. Such exemption being equivalent, in his opinion, to a direct grant by the Crown must raise the question of State control.

A FRENCH REVIEW OF SURGICAL PROGRESS.

STIMULATED by Dr. de Lavergne's account[1] of the advances made by medicine in the war, Professor Billet, also a teacher at Val-de-Grâce, has sketched[2] the astonishing improvements that this war has brought to surgery. His review is the more interesting as it is taken from a different viewpoint from that of reviews which have appeared in England, and, indeed, the only British practitioner mentioned is Sir Almroth Wright. The review may be briefly summarised thus. The great lesson taught to surgeons by the war is their personal limitation, and the need of team-work. Working by himself, the most skilful surgeon must fall short of possibilities; he therefore must accept and take guidance from other persons, experts in eyes, ears, X rays, bacteriology, chemistry, medicine, &c., if he is to do the best possible for his patients. So thoroughly has this lesson been learnt in France that the members of the profession are beginning to ask for an organisation and equipment for civil hospitals *similar to that they had found so satisfactory* when they were working in army hospitals during the war. The war began with a great surprise to the profession; it had been thought that gunshot wounds were rather slight and would heal at once. It was bullets that were thought of, it was shells which came. And just as the soldiers were overwhelmed with shell in the first days, so were the surgeons overwhelmed with septic wounds, with tetanus, septicæmia, and gas-gangrene. By the end of October, 1914, preventive inoculation had eliminated tetanus, but septicæmia and gas-gangrene remained. The *dreaded invaders* were the anaerobic bacilli. To defeat them every wound was thoroughly opened up and then irrigated with antiseptics. Results were better, but every wound suppurated and some patients died exhausted; some had to have their limbs, saved with so much trouble, amputated later. Antiseptics became suspected. Some thought they injured the tissues, some that they did not go deep enough. In August, 1915, Carrel with his tubes, Dakin with his solution, seemed to have won a complete victory. But the aseptic surgeons were still unsatisfied, feeling that antiseptics had no right to be resuscitated, and Delore in 1915 and Leribat at Verdun in 1916 told of a simpler, better, treatment for wounds of the knee. Leribat opened up the track, excised the wounded tissues, made the joint clean, washed it out with ether, put in a tiny drain (removed after 48 hours), sewed up the synovial membrane first and then the skin, put on a plaster splint for a fortnight, and discharged his patients thereafter with knees that could bend, his success being largely due to more exact technique, and to smaller, better judged incisions. In November of the same year, 1916, Gaudier extended this principle to the treatment of all wounds, and became the author of the method of "primary suture." But some wounds, already left too long, and so become infected, were unsuitable; to them Carrel's method was applied, and "delayed primary suture" became possible. Thus was ordinary suppuration defeated. There remained gas-gangrene, which proved to be beyond the power of the surgeon alone; he had to call on the laboratory for help. Still, it was not till late in 1916 that, the organisms having been isolated and an effective vaccine prepared, the last problem in the treatment of wounds was solved. Since then great triumphs have been won in repairing deformities, especially by Morestin, by autoplasty, splints or supports, and grafts. And grafts are so various. Before the war Tanton had replaced a lacerated urethra with a graft from a saphena vein; since the war Legueux has had marked success in replacing lost urethræ with arteries, living or dead. Tendons may be grafted even with dead tendon (Nageotte and Sencert), nerves repaired even with dead nerve tissue, though supports for the limbs may still be needed. As for bones, there are the three grafting methods: that of Delagenière, who uses a small superficial shaving off the bone, a graft of periosteum with a little scale of bone below it; that of Albee, who takes a piece of bone from the periosteum to the medullary canal; and that of Nageotte, who uses dead bone; and there are all sorts of combinations of the three. So much for surgical affections. But surgery can help medicine. Carrel-Dakin methods are useful in treating chronic suppurating pleurisy. As for acute pleurisy, some propose to remove it in mass, as they do tumours, and to close the wound at once. Others say drainage is useless. Ombredanne in appendicitis removes the appendix and at once closes the peritoneum; less and less do people drain the pleura with large drainage-tubes; some even talk of immediate closure once the pus is out. Next vaccines. Osteomyelitis, if chronic, yields to Carrel-Dakin, but if acute may be mastered by staphylococcus vaccines (R. Grégoire). The streptococcus is more obstinate, but is at times thus overcome. Such are the surgical advances of the war, and progress continues in peace. Nor yet has all the harvest been gathered.

THE NEWLY CONSTITUTED CENTRAL MIDWIVES BOARD.

THE Central Midwives Board has now completed its reconstitution under the Act of 1918. The initiative, it may be noted, for a wider representation originated with the Board itself, and there are now five certified midwives with seats on the tribunal. The membership is as follows, the names of new members being asterisked: Sir Francis Champneys, in the chair; Professor Henry Briggs, Lady Mabelle Egerton, *Miss Gladys Le Geyt, and *Miss M. Olive Haydon, appointed by the Ministry of Health; Dr. W. S. A. Griffith, appointed by the Royal College of Surgeons of England; Dr. J. S. Fairbairn, appointed by the Incorporated Midwives Institute; Dr. C. Sangster, appointed by the Society of Apothecaries; *Dr. J. J. Jervis, appointed by the Association of Municipal Corporations; *Dr. R. A. Lyster, appointed by the Society of Medical Officers of Health; Miss Rosalind Paget, appointed by the Queen Victoria's Jubilee Institute for Nurses; Mr. L. H. West, LL.D., appointed by the Association of County Councils; *Miss Pollard and *Miss Elizabeth Pearson, appointed by the Incorporated Midwives' Institute. Dr. Jervis is chief health officer for the city of Leeds, and Dr. Lyster for the county of Hants. Of the midwife representatives, Miss Le Geyt is superintendent of a school for mothers, Miss Haydon has charge of a midwives' training school, Miss Pollard is inspector of midwives for the county of Middlesex, and Miss Pearson has been active in organising midwives' associations in the country. It will be seen that the new constitution has resulted in a widely representative gathering and gives colour to the hope that, without neglecting the necessary but painful work of penal sessions, the Central Midwives Board may turn its attention to constructive work for the building up of a convenient and efficient midwifery service in this country. No one any longer grudges the trained midwife her place as an essential part of any public health service. The more comfort and dignity that can be brought into the midwife's life, the better will be the service offered.

THE RÔLE OF THE NERVOUS SYSTEM IN BODY TEMPERATURE REGULATION.

THE rôle of the nervous system in the regulation of temperature is known to be a very complex one. H. G. Barbour and E. Tolstoi have made experiments on dogs by placing them up to the neck in a bath at 20° C. for half an hour or more, the temperature of the room being 22° C. The water was not sufficiently cold to lower the body temperature, but distinctly aroused the regulation mechanism against cooling. There was a slight gain of 0·1° to 0·8° C. in body temperature; there was an increase of 1 to 2 per cent. in the blood solids. Similar dogs with transection of the cord between the sixth and seventh cervical segment were quite unable to withstand baths of 20° C., exhibiting a rapid fall in body temperature, usually to a dangerous level in 40 minutes. Unlike normal dogs, they failed to exhibit shivering, and all showed an abnormally low blood-solid percentage as the result of the operation. The cold stimulus was unable to evoke more than a very weak response. This inability to reduce the blood volume and thereby diminish the flow through the body surface helps to account for the very rapid loss of body temperature. Dogs made poikilothermal by cervical cord section are deprived of reactions which may be set up between the temperature sense nerve-endings and the circulation. The shifting of water from the blood to the tissues is evidently such a reaction. The authors conclude that the rôle of the nervous system in the reaction against cold is to convey impulses from the temperature sense nerve-endings to heat centres, which in turn, besides shivering and vaso-constriction, incite blood thickening. Hæmo-concentration lessens the water available either for heat dissipation by evaporation or for providing blood bulk sufficient to flood the peripheral vessels. Normal dogs respond regularly to a moderately high environmental bath temperature (40°–41° C.) by hæmo-dilution and to a cold environment (11°–8° C.) by hæmo-concentration. The change usually approximates to 2 per cent. of the total blood-weight, which means 10 per cent. change in the fluid content of the blood. The circulatory factor in regulation against overheating and cooling consists not merely in transferring of blood respectively to or from the body surface, but also in actual shifting of water into or out of the blood-stream. Thus, response to a hot environment is peripheral vaso-dilatation plus hæmo-dilution, while a cold environment evokes vaso-constriction plus hæmo-concentration.

THE ANNUAL MEETING OF THE BRITISH MEDICAL ASSOCIATION.

THE annual meeting of the British Medical Association opens at Newcastle-on-Tyne on Friday, July 15th, when the Representative Body meets at 10 A.M. and continues in session until the following Tuesday, on which day, at 2 P.M., the statutory annual general meeting will be held. Professor David Drummond is announced to give his presidential address at 8 P.M. on the same day, and on Wednesday, Thursday, and Friday, July 20th–22nd, the 17 sections will conduct their discussions, the first group on each of the three days, the second group on two days, and the third on one day only.

Group I.—Medicine: Professor Thomas Beattie.
Surgery: Professor J. Rutherford Morison.
Pathology and Bacteriology: Professor Stuart McDonald.
Preventive Medicine with Industrial Diseases: Sir Thomas Oliver.
Orthopædics and Diseases in Children: Mr. A. H. Tubby.

Group II.—Neurology and Psychiatry (July 20th and 21st): Professor A. W. Mackintosh.
Obstetrics and Gynæcology (July 21st and 22nd): Professor B. P. Ranken Lyle.
Ophthalmology (July 20th and 21st): Professor J. D. Wardale.
Oto-Rhino-Laryngology (July 20th and 21st): Dr. G. William Hill.
Physiology, Pharmacology, Therapeutics, and Dietetics (July 20th and 21st): Dr. H. H. Dale.
Venereal Diseases (July 20th and 21st): Colonel L. W. Harrison.

Group III.—Ambulance and Red Cross (July 20th): Sir James Cantlie.
Dermatology (July 21st): Dr. J. Farquhar Christie.
Medical Sociology (July 22nd): Sir Jenner Verrall.
Proctology (July 20th): Mr. J. P. Lockhart-Mummery.
Radiology and Electro-Therapeutics (July 22nd): Dr. Robert Knox.
Urology (July 22nd): Mr. J. W. Thomson Walker.

On Wednesday, at 8 P.M., Sir Thomas Oliver will give an address on Industrial Diseases, and on Friday, at 7.30 P.M., Professor Arthur Keith will deliver a popular lecture on Evolutionary Wounds. The annual dinner of the Association is fixed for Thursday at 7.30 P.M.

CANCER IN ANIMALS.

AT a recent meeting of the Académie de Médecine Mr. Cadiot read an interesting paper[1] on the distribution of cancer in animals, utilising a number of facts and figures taken from the literature in order to draw conclusions on some of the general problems of cancer. From the fact that carnivorous and herbivorous animals show no great difference in the incidence of cancer, the author deduces that diet does not constitute an important factor in the genesis of cancer. Age, in animals as in man, stands out as the predominating factor. There are, however, interesting differences in the incidence of cancer in so far as it affects the different organs, and these differences also exist between different species of animals. Thus cancer of the penis appears to be particularly frequent in horses, and according to the author occurs most frequently in castrated animals. In oxen the atrophy of the testicles, which takes place after castration by "twisting," presents a predisposing factor for the development of malignant growths, chiefly of a sarcomatous type. The author is, however, on very debatable ground when he tries to prove from the incidence of cancer in animals that chronic irritation is of comparatively little importance. He bases his argument chiefly on the assertions that cancer of the digestive tract of animals is very rare, and that in draught animals cancer of the skin does not develop in those sites where the pressure of the collar and the friction of the harness produce a chronic irritation. A glance at the tables published in the Third Scientific Report of the Imperial Cancer Research Fund entitled, "Malignant New Growths in Domesticated Mammals," shows that cancer of the digestive tract is not as infrequent as Mr. Cadiot believes it to be. And he must surely have forgotten the "horn core" of cattle in India, where a squamous cell carcinoma develops with great frequency at the root of the right horn in cattle employed for draught purposes, the right horn being used to attach the animal to the wagon. But the whole question of the relation of chronic irritation to the causation of cancer has during the last few years been raised from the slough of argument and placed on a secure basis by experiment. The work of Fibiger on the experimental production of cancer of the stomach by feeding with spiroptera, and the experimental production of cancer by prolonged painting with coal tar —first successfully demonstrated by Yamagiwa and Ichikawa, and since confirmed by Fibiger and by Murray and Woglom in this country—represent important advances of our knowledge of the origin of cancer. A grain of experiment, properly conducted, is worth at least an ounce of argument.

THE CASSEL HOSPITAL.

THE Cassel Hospital for Functional Nervous Disorders will shortly be ready for the admission of patients, with Dr. T. A. Ross as medical director; the medical committee includes Miss Aldrich-Blake, Dr. Farquhar Buzzard, Sir Maurice Craig, Lord Dawson, Professor J. S. Haldane, F.R.S., Dr. Henry Head, F.R.S., Dr. A. F. Hurst, and Sir Frederick Treves. Patients eligible for admission are members of the educated classes who are suffering from neuroses not directly traceable to organic disease, who cannot afford treatment in a nursing home. The hospital is situated among beautiful surroundings at Penshurst, Kent, and there will be accommodation for 60 patients, who will be asked to contribute only towards maintenance. In medical circles the want of private hospitals for educated patients unable to meet the expense of nursing homes, most of which are run on a comparatively small scale, has long formed a subject of comment. From time to time schemes for such establishments have been devised, but seldom, we believe, in the end proceeded with. The Cassel Hospital, accordingly, will really meet a long-felt want, and the success which it will doubtless enjoy should provide an impetus to further advance along similar lines. Obviously, sufferers from one or other kind of neurosis form but a part of that large class who hitherto have had only the Hobson's choice of a nursing home which they cannot afford or a general hospital where little or no special provision for private cases is made. Though in some parts of the country nursing homes of a sufficient size almost to justify their description as private hospitals have been springing up to meet the need, with them the expense of running the establishment must always militate against the maintenance of fees at a comparatively moderate level. This aspect of the problem, through the generosity of its founder, would appear to be satisfactorily settled as far as the new Cassel Hospital is concerned. From the standpoint of therapy there are advantages in the segregation of patients whose complaint is of "nerves" in any form, since they will be free from the adverse influence, on the sensitive mind, of contact, direct or indirect, with the mixed medical and surgical cases of general hospitals. On the other hand, too sheltered a life in a secure environment of comfort and beauty brings its own danger in removing the incentive to cope with the adverse conditions of real life. However, once let the proper atmosphere of cure be created in such a private hospital and it is bound to prove worthy of the hopes at present centred in it.

Dr. Sidney Reginald Dyer, Medical Inspector of Prisons, has been appointed one of the Commissioners under the Prison Act.

THE House and Library of the Royal Society of Medicine will be closed from Saturday, May 14th, until Tuesday, May 17th, both days inclusive.

MEDICAL STATISTICS.

I.

IN these days when the expediency of compiling and analysing clinical records is debated, it is fitting to inquire into the past relations between medical and statistical science. Is the application of the numerical method to the subject matter of medicine a trivial and time-wasting ingenuity as some hold, or is it an important stage in the development of our art, as others proclaim? An answer to this question must needs be coloured by individual predilection, but a brief retrospect of medical history will provide certain data of value in reaching a decision. On this account we propose to notice some incidents which have rather tended to pass out of the memories of the present generation, to display the connexion between the progress of medicine and the progress of a department of knowledge which seems at first wholly alien from it.

Historical Retrospect.

The great Hippocrates has received many titles of honour from an admiring posterity, but that of statistician has not been included. Yet the student of his "genuine" works will find therein much which is uncommonly suggestive of a statistical method. We do not refer to the collection of cases upon the strength of which Sir Gilbert Blane attempted to assess the fatality of untreated "fevers," but to the insistence upon a synthesis of individual experiences as the preliminary of any general theory, whether of epidemiology or endemiology. This side of the Hippocratic doctrine was the stock-in-trade of the Empiric sect, who, indeed, according to their impartial critic, Celsus, and their by no means impartial critic, Galen, would believe in nothing unless it were supported by an array of evidence which was statistical in all but name. The works of the Empirics have perished, and Galen set himself to blacken their reputation, with such success that the term became a synonym for quack. No massed clinical records other than those of Hippocrates himself have come down to us.

When Sir Gilbert Blane wished to compare his experience with that of the ancient masters, he could do no better than contrast statistics of his hospital and private practice with the records appended to the third book of Hippocrates's epidemics. The same remark applies to the experience of preventive medicine which must have been acquired through the centuries of Roman civilisation. Sir John Simon[1] and others have pointed out that in the best days of Rome public hygiene and preventive medicine were a care of the legislature, but of the successes and failures of the system we know nothing. The normal death-rate, its relation to urbanisation, the influence of employment, the toll taken by epidemics, these things are matters of conjecture.[2] Of the theoretical basis of ancient medicine we know much, of its practical consequences hardly anything. Nor when we turn to modern times, to the practice of medicine from the Renaissance down to the end of the seventeenth century, is the case much better. The physician of the middle of the seventeeth century had indeed abandoned some superstitions of Chaucer's Doctor of Physik, but he was not perhaps a much more scientific or efficient practitioner. Indeed, so ripe a scholar and merciful a critic as the present Harveian Litrarian has said of a still more recent generation that "the doctors were still engaged in speculating in the quiet of their studies instead of seeking for information in the book of Nature."[3]

The greatest English physician of that age clearly appreciated the defect, and his Medical Observations aim at restoring the ancient Empiric tradition. Sydenham was contemptuous of theory, and had little—too little—respect for the experimental researches of his best contemporaries. He provided medical records, statistics of disease without arithmetic. No doubt he was acquainted with the political arithmeticians of his day, as he was with the experimental philosophers and anatomists, but he did not adopt their method in presenting his facts. It is instructive to compare his direct influence upon the development of medical science with that of a non-medical contemporary.

Vital statistics of a kind had been regularly compiled in London for a century before Sydenham's time, but no real use had been made of them by physicians. Indeed, no physician of Sydenham's time exploited them; the *medical* pioneer was the elder Heberden, who, in the middle of the eighteenth century, financed and otherwise encouraged a compilation of the bills upon which his son at the beginning of the nineteenth century wrote a dissertation, to be mentioned below.

John Graunt: The Father of Medical Statistics.

But there was in the seventeenth century a layman who perceived the importance of medico-statistical records. John Graunt, the London draper whose "Natural and Political Observations upon the Bills of Mortality" first appeared in 1662, was the father of medical statistics as well as of vital statistics in the larger sense. He was not only the first to demonstrate the high rate of mortality in early life and the contrast between urban and rural rates of mortality (facts so commonplace to us that we forget they were ever novelties and in need of proof), but he undertook a criticism of sources which some persons of our own time suppose to be beyond the range of a mere arithmetician. He would not, for instance, accept rickets as a "new disease" of the year 1634 without asking himself whether it might not be that a disease "which had been long before, did then first receive its name?" and surmised that some, but not all, the increase was due to a transfer from another rubric. In truth a comparison of the criticism of his nosological material performed by the seventeenth century draper with that effected by an erudite physician at the beginning of the nineteenth century does no dishonour to the old tradesman.

Dr. William Heberden the younger, in his "Observations on the Increase and Decrease of Different Diseases," remarked that "there is scarcely any fact to be collected from the bills of mortality more worthy the attention of physicians than the gradual decline of dysentery," and attributed the result to greater cleanliness and better ventilation. As Dr. Charles Creighton pointed out,[4] the decline of dysentery needed no such explanation; it was an arithmetical mistake. Heberden supposed that "griping in the guts" was dysentery when it really was infantile diarrhœa; he overlooked the significance of the age distribution and failed to observe the gradual transfer to the rubric convulsions. He did indeed notice the increase of convulsions but accounted for it by a transfer of "chrisomes" and infants, without remarking that this transfer had already been effected before convulsions gave a large quota, and without perceiving that such a transfer could not make so great a change as had occurred.

The vital statistician who connects Graunt with Halley and Halley with other illustrious mathematicians like De Moivre and the Bernoullis, these mathematicians with the technicians Gompertz, Finlaison, Makeham and the actuaries of our own time, will not fail to do reverence to the seventeenth century pioneer. The medical statistician and the medical officer of health should remember that Graunt inspired Derham, that Derham was the original of Süssmilch, and that Süssmilch supplied Malthus with ammunition, the discharge of which did much to create a state of opinion favourable to the establishment of a national system of vital and medical statistics.

But if ultimately Graunt had a worthy disciple in the medical profession, it was not until he had been in his grave more than a century. He died in 1674 and

[4] History of Epidemics in Britain, vol. ii., p. 747.

William Farr was born in 1807. The only physicians of the eighteenth century who made sensible additions to statistical knowledge were Dr. Thomas Short and Dr. William Heberden the elder. Of Short Dr. Creighton has remarked, with little charity but not without truth, "That so much statistical or arithmetical zeal and exhaustiveness should go with so total a deficiency of the critical and historical sense, is noteworthy and, perhaps, not unparalleled in modern times."[5] To Heberden we owe the collection of statistics edited by Corbyn Morris[6] in 1759, incorporating some excellent critical remarks and suggestions for improvement of the civic records which did not receive the attention they deserved. No other physicians seem to have perceived that a combination of Graunt's arithmetical system with the descriptive method of Sydenham—in short, to mix figures with brains, as Turner compounded his colours—would advantage medical science and art. What was speculative in Sydenham's plan—and there was a good deal more theorising in it than many suppose—found plenty of imitators. Whether the general art of medicine benefited, the reader of Dr. Chaplin's FitzPatrick lectures may judge. Whether the sanitary administration of the late eighteenth century was a notable improvement upon that of the Stuarts is a question the student of Creighton and Simon can answer with no great confidence.

At the beginning of the nineteenth century we still lacked any clear portrayal of the sanitary circumstances of the population. The prevalence and the fatality of the commonest diseases were still matters of conflicting opinion. Instructed observers could, and did, dispute whether consumption were increasing or decreasing, just as but a few years earlier they differed by 100 per cent. in their estimates of the English population.

II.

Although Sir Gilbert Blane, in his "Select Dissertations," published statistical observations of value, and Dr. Bissett Hawkins actually devoted a course of Goulstonian lectures to the arithmetic of disease before George IV. was dead, Heberden's "Observations" of 1801 are still the only medico-statistical literature before Farr which deserve much notice.

We have previously mentioned one of Heberden's failures; it would be wrong, even in so brief a review, to omit reference to his successes. An instance was his recognition of the constancy of the epidemic curve of plague which led him to make the following pertinent remark:—

> "May not this influence of the seasons on diseases be the real cause of the strange and contradictory accounts we have received concerning the cure of the yellow fever in the West Indies? Accounts which only agree in this, that the most obvious methods of treatment are wrong. It is reasonable to suppose that physicians there would first make trial of the remedies most approved in similar diseases in other places; yet we find they all failed. And why? Because the epidemic was then at its height. But afterwards, all their different modes of practice as universally succeeded. For when the disease began to decline, the mortality of itself became much less, and of those who died, most lingered on for a considerable time beyond their usual period. Which exactly corresponds with what has at all times been reported of the plague, under every variation of medicine, and climate."[7]

Many physicians since 1801 have had cause to realise the truth of this statistically grounded inference; its general appreciation would have diminished the large and growing number of tombstones sacred to the memory of "cures."

"*Mr. Farr: A Gentleman of the Medical Profession.*"

But one swallow does not make a summer, nor the statistical acumen even of a Censor of the College in its most aristocratic days effect a revolution. The real revolutionary was a licentiate of the Society of Apothecaries, a "Mr. Farr, a gentleman of the medical profession," who was appointed Compiler of Abstracts in the General Register Office on July 10th, 1839. Although Mr. Noel Humphreys earned the gratitude of all medical men by his collection of Farr's writings, published in 1885, a really adequate edition of Farr has yet to be produced. We sometimes dream of such an edition; we picture it with an introduction by Farr's worthy successor, Dr. Thomas Stevenson, and with footnotes and appendices by Dr. John Brownlee. But it is an idle dream; governments in England, so the newspapers tell us, often spend money in odd ways, but at least they have never been so eccentric as to waste it on the publication of the collected works of great Englishmen. Farr was a very great Englishman, and the characteristics of his genius were precisely those which, in moments of self-esteem, we like to fancy are typically English. We can make our point clear by contrasting him with two great men who were at their prime when he was young, and both made important contributions to statistical knowledge, Siméon Poisson and George Boole. Poisson wrote a large treatise upon ostensibly the most practical of subjects, the best way to secure just verdicts in courts of law; Boole dealt with the very matter-of-fact problem of numerical approximation. But the most superficial reader of Poisson or of Boole—not that their works are very attractive to a hasty reader—will at once realise that the authors are far more interested in algebra than in the concrete applications of their algebra. Farr has left many pages which, to the aforementioned hasty reader, will offer almost as many algebraical difficulties as even Boole; but in the densest forest of symbols Farr never loses sight of, and never allows his companion to lose sight of, some perfectly definite and concrete end which he proposes to reach.

No branch of medical or vital statistics needs for its cultivation a greater variety of algebraical tools than that concerned with the production of complete life tables; the natural faculty which characterises the born mathematician is not, indeed, essential, but skill in the manipulation of symbols is. To Farr a life table was—

> "An instrument of investigation; it may be called a *biometer*, for it gives the exact measure of the duration of life under given circumstances. Such a table has to be constructed for each district and for each profession, to determine their degrees of salubrity. To multiply these constructions, then, it is necessary to lay down rules, which, while they involve a minimum amount of arithmetical labour, will yield results as correct as can be obtained in the present state of our observations.[8]

This was the spirit of all his work. He faced mathematical difficulties with a courage which nothing could daunt—it takes some courage for a self-taught man to venture upon original research within the province of the oldest of the sciences—when they obstructed his progress towards a practical end. He never attempted to compete with the masters of pure analysis on their own ground. We have been the gainers. The greatest mathematical statisticians of the first half of the nineteenth century were not Englishmen; we have not to our credit any theoretical work of that date which will compare with the researches of Laplace and of Poisson in France or of Gauss in Germany; but of no civilised country can a record of fatal disease be constructed with the precision which appertains to the medico-statistical history of England and Wales since 1840.

The practical advantages to the physician and the sanitarian are enormous. Matters which our great grandparents fiercely debated, topics respecting which only a very shrewd and experienced physician of 1820 could form an opinion, are now within the compass of a junior medical student. If Farr had been born a generation earlier and the General Register Office had been founded in 1807 instead of in 1837, the sanitary history of our manufacturing towns might have been different. If even the lessons he taught year by year had sunk into the minds of all members of our profession, many disappointments would have been spared and perhaps some false apprehensions quieted. The curious reader of old blue-books will find much of interest in the census reports of Lamb's friend Rickman, but Rickman was not a Farr. Rickman, for instance (in 1831), commented upon the apparent unhealthiness of the northern manufacturing districts, but he could not speak with much authority for his basis of facts was no more than an abstract of burial and baptismal registers. These are the words of Farr (from the supplement to the thirty-fifth Annual Report):—

[5] History of Epidemics in Britain, vol. i., p. 405.

[6] The origin of the work is described in Dr. Hull's edition of the Economic Writings of Sir William Petty, vol. ii., p. 641.

[7] Observations on the Increase and Decrease of Different Diseases, 1801, p. 67.

[8] From a paper contributed to the Proceedings of the Royal Society in 1859. (See Farr's "Vital Statistics," ed. Humphreys, London, 1885, p. 492.)

> "Take for example the group of 51 districts called healthy for the sake of distinction, and here it is found that the annual mortality per cent. of boys under 5 years of age was 4·246, of girls 3·501. Turn to the district of Liverpool; the mortality of boys was 14·475, of girls 13·429. Here it is evident that some pregnant exceptional causes of death are in operation in this second city of England. What are these causes? Do they admit of removal? If they do admit of removal, is this destruction of life to be allowed to go on indefinitely? It is found that of 10,000 children born alive in Liverpool 5396 live five years, a number that in the healthy districts could be provided by 6544 annual births."

The "dear old doctor"—as Mr. Humphreys called him—could round a period in the early Victorian style with the best; the classical quotations in his reports might have tempted William Pitt or Charles Fox to become statisticians; but he could also use very plain English indeed. Statistics with plain English as a propellent are formidable missiles, and those members of our profession who in the last 50 years have effected salutary changes in the second city of England (there is still much to do) owe something to the long-range artillery of the General Register Office.

We could fill many columns with examples, but we must take leave of the greatest of medical statisticians with one observation. Farr's work has on it the seal of all supreme achievements; it is indestructible. It was, of course, a piece of good luck that his three successors, the late Dr. William Ogle, Dr. John Tatham, and Dr. Thomas Stevenson were men having the same ideals and zealous to build higher upon his foundations. The nation, we hope, will always be fortunate enough to secure equally worthy spiritual descendants of the founder. But no weakness of human instruments or credible deteriorations of the system could ever take from the General Register Office the power of "rendering immense service to sanitary science by enabling it to use exact numerical standards in place of the former vague adjectives."[3] So far as records of mortality are concerned, the real reformer is one who treads accurately in the footprints of William Farr.

III.

We have seen what, in the hands of a man of genius, the arithmetical method can contribute to the practical arts of the sanitarian and the clinician. It replaced, in Simon's phrase, "vague adjectives" and indecisive controversies by "exact numerical standards." It not only showed which municipal sheep were black, but measured how much blacker they were than their neighbours. It showed not, perhaps, what diseases (or, if we please, symptom-complexes) were most deadly, but certainly what diseases educated men supposed to be most deadly. Incidentally, it has furnished the high-browed or, if the reader prefers, sagacious epidemiologists who revere Sydenham and his epidemic constitutions with some of their best arguments. But the praise of our fathers which begat us cannot be the last word of science, nor is it the best compliment to our fathers. It is proper to consider what they did not do and whether we should not set about the task.

The Correlation of Morbidity with Mortality.

Farr once remarked that "the mean lifetime of a generation may be the same, and yet the several lifetimes of the individuals of which it is composed may vary infinitely," and spoke of the "entire revolution in the life of the human race" which "would follow if every person born lived the average lifetime of 50 years, or if half the deaths happened in infancy and the other half at the end of 100 years or at any very advanced age." He means that such a statistical average as the expectation of life might arise in an infinite number of ways, each corresponding to a different state of affairs. Still using mortality records as our ultimate data, we can explore many of these possibilities, but so long as we are restricted to death registers we must remain ignorant of much which we desire to know.

We are given that A B died at 31, C D at 32, and E F at 34, all of organic disease of the heart, and the statistician enters three units in the age-group 25–35; but how very different may be the histories of these three individuals. One perhaps, has been a dyspnœic cripple for years and died by inches; another has passed out of existence in a flash with a ruptured aneurysm, and the third—why the third may have been a psychopath. A statistical homogeneity in the matter of dying may conceal a very wide heterogeneity in the matter of living.

> "A king of ability or an able minister" said Bagehot, "sits in an orderly room filled with memorials, and returns, and documents, and memoranda. These are his world; among these, he of necessity lives and moves. Yet how little of the real life of the nation he governs can be represented in an official form! How much of real suffering is there that statistics can never tell! How much of obvious good is there that no memorandum to a minister will ever mention! How much deception is there in what such documents contain!"

This criticism touches any attempt to evaluate the health of a nation wholly in terms of its mortality. Farr, of course, was quite conscious of the weakness, and strove ever and again to overcome it, to correlate morbidity with mortality. But he could not effect a satisfactory correlation, and now, nearly forty years after his death, we are still at a loss.

We may look at this matter from two points of view. In the first place we may inquire into the general efficiency of a population. We may seek to know how many of the days from birth to death were passed in the enjoyment of health. This is the easier and perhaps the more important task. The operations of private or public sickness insurance institutions have, in fact, already rendered available much information. Yet even here there are difficulties; there must be some objective criterion of healthiness, and if this is to be, as it usually must be, capacity to follow an occupation, we are liable to fall into serious mistakes. It does not follow that, because a judge of the High Court keeps his house with a cold and a solicitor does not, judicial duties are more unhealthy than the drawing of briefs. But this aspect of morbidity, although it concerns the medical profession, is not wholly their business, indeed, some actuaries have doubted whether it is their business at all. These actuaries were, no doubt, in error, but considerations of space induce us to pass at once to the other question which is exclusively medical, and to ask whether the arithmetical method applied to other data than recorded deaths can be of any service to the clinician.

Those who remember a charming essay of the late Sir William Osler on an Alabama student will recall his remarks upon Louis, who was addicted to the numerical method. But few have the patience or the opportunities of Louis; one has to consider the conditions of ordinary medical practice. Patients come to us with symptoms, not with diseases; they very often say, "Doctor, I've got a heavy cold on me," very rarely, "I'm afraid I am infected with the *Micrococcus catarrhalis*."

"Colds" from the Statistical Viewpoint.

"Colds" are certainly an object of statistical interest if numerical frequency is an element of statistical interest. Now the "cold" may be a "Ding an sich" or it may be the prelude of a more important "Ding." Perhaps it may be suggested that an enumeration of the "colds" which did and those which did not lead up to something else might be the basis of a statistical inquiry. But the research does not seem a promising one. It might enable the practitioner confronted with a husky panel patient to assert that the chance is 1 in 100 that he will soon have to treat him for phthisis, 3 in 100 that lobar pneumonia will develop, and so on, but this arithmetical information will gratify nobody save a chimera identified by the cartoonist of the *Daily Mirror* with an official of the Ministry of Health. But if one collected statistics of "colds" upon a slightly different plan the results might be more rewarding. Do the "colds" of sedentary workers last longer than those of out-door workers? *Ceteris paribus*, does keeping the house answer better than going out? Is it true that "summer colds" are the most intractable? Is the mode of onset of a common "cold" of any importance in its prognosis as to severity and duration? Is there a secular change of type in the common "cold"? These are all questions not of life and death, but of importance to health and happiness. It is difficult to see how they *can* be answered unless the numerical method brings into this humbler sphere that replacement of "vague adjectives" by "exact numerical standards" of which Simon spoke. The common "cold" has been termed the opprobrium of the profession; perhaps we have held our heads too high and dreamed too many bacteriological dreams, forgetting that the first word must be said before the last can be added.

---

[3] Simon: English Sanitary Institution, p. 212.

It will be urged that we all have very decided opinions, grounded on our individual experiences, as to how each of these questions could be answered. So had our predecessors upon the topics of urban and rural mortality, upon the increase or decline of phthisis. But yet, as Simon pointed out, it really did require a Farr and the numerical method to produce anything like unanimity of opinion upon these matters. The Odes of Horace are better reading than the remarks of Cæsar on the Gallic wars, but it is well to read the Gallic wars before tackling Horace. No arithmetical averages, not even with their "probable errors" ground out to the last decimal and flanked with algebra of the most imposing unintelligibility, can be a substitute for the clinical researches of a Sir James Mackenzie; but they may serve as stepping-stones along a path which many have shunned and in which others have stumbled. The plain fact is that much the greater part of the clinical experience gained by each generation dies with its possessors. Much is in truth incommunicable; we profit very little, and can profit very little, from the mistakes of our fathers. But a residuum *is* communicable and has been lost because there has been no common medium of exchange.

A Ministry of Health Scheme.

A few months ago a committee appointed by the Minister of Health projected a scheme by means of which it was intended to make the communicable experience of all available to all. With the question whether the details of this scheme were good, bad, or indifferent we have here no concern. But the manner in which it was criticised, the principles of the opposition to it, revealed, as we think, a strange ignorance of the history of our art and of the means by which it has been improved. The historical importance of such men as Sydenham and Huxham was due to their determination to describe and record objectively the facts of their experience. "He strove," said Haeser, in the most discerning criticism of the English Hippocrates which has been produced, "not to discover mysterious arcana. but by the attentive observation of diseases, especially of the commonest sorts, to discern the nature of changes at the back of them, their being (Wesen), and by means of knowledge thus won to discover how to treat them."[10] But without the stepping-stones, the aids to clear thinking, which arithmetic affords the physician just as it does the statesman, these efforts fail. The medical officer of to-day finds Graunt more intelligible and helpful than most clinicians find Sydenham. Arithmetic, or even algebra, is a bad master, but it is a good servant. When this truth has been realised, the question of medical records will appear in better perspective and the possibility of clinical research, not for the gifted few alone, but for all, will be admitted.

---

THE HORSLEY MEMORIAL.

THE *organisation formed in November, 1920, to secure* in permanent form the recognition of the life and work of Sir Victor Horsley has now published a third list of subscriptions, promised and received, as follows:—

	£	s.	d.
Mr. L. H. S. Scott	25	0	0
Dr. J. S. Risien Russell	21	0	0
Dr. Janet E. Lane-Claypon, Dr. Foster Kennedy (New York), Dr. Herbert Spencer, Dr. Charles Hamilton, Dr. G. G. Turner, Mr. Percy Flemming, Dr. N. S. Finzi, Sir William T. Lister, Mr. Bilton Pollard, Dr. L. Gordon Hopkins, Dr. J. H. Parsons, F.R.S., Dr. Dennis Embleton ... ... each	5	5	0
Mr. H. J. Spratt, Mr. John Dilloy... ... ... each	5	0	0
Anonymous (per Dr. H. Batty Shaw), Dr. Hyde Marriott, Miss P. Whitaker, Professor T. R. Elliott, F.R.S., Dr. A. M. H. Gray, Dr. T. H. Ionides, Dr. G. E. Waugh, Dr. Amand Routh, Sir John Williams, Dr. R. H. Marten (Adelaide) ... ... each	3	3	0
Professor Winkler (Utrecht)	3	0	0
Dr. E. D. Davis, Dr. Byrom Bramwell, Dr. E. Deanesly, Mr. W. Gifford Nash, Sir E. Sharpey Schafer, Dr. H. C. G. Semon, Dr. A. G. Phear, Sir John Tweedy, Dr. J. H. E. Brock, Dr. A. J. Blaxland, Dr. B. B. Gadgil, Dr. F. G. Penrose ... ... each	2	2	0
Dr. Charles Brook, Professor W. W. Keen (Philadelphia), Dr. A. A. Lendon (Adelaide)... ... ... each	2	0	0
Sir James Barr, Dr. J. J. Powell, Dr. Charles Smith, Dr. E. B. Ffennell, Miss Kirkaldy, Dr. Seymour Taylor, Dr. G. Hall, Dr. W. S. Sheldon, Dr. Howell Rees, Dr. D. Farnell, Dr. E. H. Young, Mr. E. A. Bullmore, Surgeon-Commander C. B. Fairbank, Dr. W. H. Paine, Dr. J. S. H. Roberts, Dr. S. Williams, Dr. O. P. Turner, Dr. C. D. Holdsworth, Dr. P. J. Le Riche, Dr. G. H. Hunter ... ... each	1	1	0
Miss M. Breay, Miss M. K. Longfield... ... ... each	1	0	0
Miss M. Lord	0	5	0
Mrs. Pitt	0	2	0
Dutch Branch of International League against Epilepsy (per Dr. Muskens)	1	0	0
Society for the Prevention of Hydrophobia (per Mr. F. W. Fletcher)	5	5	0

The total acknowledged in previous lists is £606; these lists appeared in THE LANCET, 1921, Jan. 1st, p. 46, and Feb. 19th, p. 407.

Further subscriptions may be paid to either of the hon. treasurers, Sir Frederick Mott, K.B.E., Maudsley Neurological Hospital, Denmark Hill, S.E.5, and Dr. H. H. Tooth, C.B., C.M.G., 34, Harley-street, W.1, or to the hon. secretaries, Sir W. Arbuthnot Lane, Bart., C.B., 21, Cavendish-square, W.1, and Mr. Edward J. Domville, O.B.E., Symondsbury, Bridport.

URBAN VITAL STATISTICS.

(Week ended April 30th, 1921.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate population estimated at 18½ million persons, the annual rate of mortality, which had been 12·5 in each of the three preceding weeks, was again 12·5 per 1000. In London, with a population of 4½ million persons, the death-rate was 12·1, or 0·5 per 1000 below that recorded in the previous week, while among the remaining towns the rates ranged from 6·4 in Grimsby, 6·5 in Rhondda, and 7·3 in Northampton, to 19·4 in Barnsley, 20·4 in Oldham, and 21·8 in Dewsbury. The principal epidemic diseases caused 204 deaths, which corresponded to an annual rate of 0·6 per 1000, and comprised 60 from infantile diarrhœa, 54 from whooping-cough, 40 from diphtheria, 33 from measles, 14 from scarlet fever, and 3 from enteric fever. Measles caused a death-rate of 1·1 in Newcastle-on-Tyne, 1·2 in Gateshead, and 1·4 in Barrow-in-Furness. There were 3255 cases of scarlet fever, 2453 of diphtheria, and 1 of small-pox under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 3307, 2564, and 0 respectively at the end of the previous week; the case of small-pox was admitted from Holborn. During the week ended April 23rd only 1 case of encephalitis lethargica belonging to Southwark was notified in the County of London. The causes of 27 of the 4460 deaths in the 96 towns were uncertified, of which 6 were registered in Birmingham and 3 in South Shields.

Scottish Towns.—In the 16 largest Scottish towns, with an aggregate population estimated at nearly 2½ million persons, the annual rate of mortality, which had been 15·1, 14·6, and 14·6 in the three preceding weeks, rose to 15·0 per 1000. The 321 deaths in Glasgow corresponded to an annual rate of 15·2 per 1000, and included 30 from whooping-cough, 6 from infantile diarrhœa, 2 each from scarlet fever and diphtheria, and 1 from enteric fever. The 123 deaths in Edinburgh were equal to a rate of 14·4 per 1000, and included 3 from diphtheria, 2 from measles, and 1 from infantile diarrhœa.

Correspondence.

"Audi alteram partem."

THE QUESTION OF A TRADE-UNION IN MEDICINE.

To the Editor of THE LANCET.

SIR,—Every right-minded practitioner must agree that a strike among medical men, involving the neglect of patients, is unthinkable. But there is another aspect of the subject which has, perhaps, been overlooked. Doctors are a State-protected body, and, that being so, have they the moral right to use the strike weapon? The police are not allowed to use it, and if the miners were to get their wish—State protection—the right to strike would have *eventually* to be taken from them. Eventually, for no Conservative, Liberal, or Coalition Government would be likely to pass such a measure; but when the Labour Government comes it will probably find itself obliged to do so. Russia has already found the necessity of such legislation. Would it not be a pity to have to wait for a Labour Government to teach us the difference between right and wrong?

I am, Sir, yours faithfully,

Keswick, May 1st, 1921. W. D. ANDERSON.

THE INTERNECINE VENEREAL CAMPAIGN.

To the Editor of THE LANCET.

SIR,—I have studiously abstained from controversy and have for several months past, as letters in my possession prove, been engaged in frank and friendly discussion both with Lord Willoughby de Broke, and other members of his Society, in an endeavour to end the schism that is doing much harm to the warfare against venereal diseases. I feel bound now to point out to the public that two things only hinder the progress of negotiations. First the sending of letters to the press by the same post as that by which they have been sent to me—a discourtesy which has twice taken place and makes frankness impossible; and secondly, and more seriously, the undeviating way in which the *Times* has given publicity to Lord Willoughby de Broke's Society, and suppressed—or most misleadingly summarised—the attitude of the National Council.

An instance of its partiality occurred on the publication of the report of the Bishop of Birmingham's Committee. This was at once described by the *Times* as the case of the Society for the Prevention of Venereal Disease, a parenthetical comment which the most prominent member of that Society admitted to me to be incorrect. An even worse instance has just occurred. The *Times* has quoted at length from a letter sent to me by Lord Willoughby de Broke, and has not quoted—and has never done other than very briefly and misleadingly summarised—the definition of the National Council's policy to which Lord Willoughby de Broke's letter was in reply. It has refused to publish the letter I at once wrote, even though I was drawing attention to action for which Lord Willoughby de Broke has subsequently expressed full and frank regret.

It is time that the public understood the reason; no one can be impartial on a matter he has already prejudged, and the "Medical Correspondent" of the *Times* who comes before the public anonymously as an impartial commentator is a member of Lord Willoughby de Broke's Executive Committee.

In these circumstances, I ask permission to state in your columns what I am refused permission to state in the *Times*—namely, that between the policy of the National Council, as defined at our general meeting on March 22nd, 1921, and that of Lord Willoughby de Broke's Society, there is now admitted to be but one real point of difference; that lies in the inability of the latter to accept the following sentences of our definition of policy:—

"Detailed official instructions as to the use of disinfectants in this connexion will, if issued to the public on sale with the disinfectants, not only have an appearance of official condonation but also lead to the assumption that such disinfectants are an official guarantee to the purchaser against contracting disease; moreover, such instructions, unless followed with scrupulous exactness after definite and personal tuition in their practice, may lead to an aggravation rather than a diminution of the incidence of these diseases."

Nevertheless, these sentences express not merely the truth, but the truth which is daily receiving greater recognition, and I have no doubt whatever, that even in spite of suppression and misrepresentation, truth will continue to prevail. I am even hopeful that Lord Willoughby de Broke, who has been frank and courteous throughout all our conversations, when allowed to speak through his own voice, will find the courage to shake himself free of the influences which are alone keeping the schism open, and so enable it to be harmoniously closed, to the great advantage of the campaign which we both have sincerely at heart.

I am, Sir, yours faithfully,

GORELL,
President, National Council for Combating Venereal Diseases.
May 2nd, 1921.

*** From an implied personality in this letter two reflections may arise. First, it is an assumption that "Our Medical Correspondent" in a lay paper is an individual. Secondly, a "correspondent" does not dictate the editorial policy of a journal.—ED. L.

THE TREATMENT OF DIABETES MELLITUS

To the Editor of THE LANCET.

"Be not the first by whom the new is tried,
Nor yet the last to cast the old aside."

SIR,—Pope's advice may be taken to apply to the medical practitioner. This letter is a plea to every practitioner not to be the last to cast aside the old treatment of diabetes mellitus by continuing to prescribe a diet of unlimited protein and fat. It is no easy matter to decide whether fat or protein in unlimited quantities is the more injurious, although there is little doubt that excessive fat ushers the young patient into the next world more rapidly than excessive protein, by causing an early and often fatal acidosis. Unlimited or excessive protein is more insidious in its action. The patient does not die rapidly, but the disease advances rapidly and a stage is reached in which the changes in the pancreas are so profound that treatment by alimentary rest and under-nutrition is rendered nugatory. The observations upon which statements are made should always accompany these statements. Shortly after adopting the Allen treatment of diabetes mellitus in 1915, I found that the cases which reacted best to the treatment were comparatively young people who had developed the disease recently, and that those who had been treated by the so-called Pavy treatment for months or years had very low tolerance for food in general; that is to say, that unless the amount of the carbohydrate, protein, and fat in the diet was very small, sugar persisted in the urine, the blood sugar was over 0·18 per cent., and the disease progressed. Still further, one received the impression that the patients who had adhered most strictly to the orders of their medical advisers to refrain from any food containing carbohydrate, and had taken large quantities of breads and biscuits made with protein, were the most refractory to treatment.

Clinical observation anticipated experimental evidence. Allen[1] recorded his observations upon dogs of the results produced by protein excess. He removed six-sevenths of the pancreas from a dog: for three days there was glycosuria without feeding. Upon a meat diet there was a heavy continuous glycosuria, and when this diet was maintained for some time it led to a condition which did not yield to a nine days' fast. Since the same observer has kept dogs alive for six years with no greater proportions of pancreas he concludes that "the downward progress observed in animals on excessive diets is purely the result of food injury; in other words, to functional over-stimulation of the pancreas as an endocrine organ." It is therefore clear that as soon as the diagnosis of diabetes mellitus has been established in a young subject a diet restricted in every way should be ordered, preparatory to making arrangements for estimating the optimum diet; and on no account should unlimited proteins be allowed either as meat or special breads, or in any other form, lest the excess of protein cause an inflammatory change in the pancreas, which materially diminishes the chance of prolonging the patient's life.

---

[1] The Journal of Experimental Medicine, May 1st, 1920.

In my opinion, placing a young diabetic upon a diet with unlimited fat and protein is like treating an early case of carcinoma of the sigmoid with hyoscyamus—the symptoms may be alleviated for a time, but when intestinal obstruction occurs it is found that the growth has extended too far to permit of removal, and the patient's life can be prolonged only slightly. When a young diabetic is treated with unlimited protein the disease extends too, and upon the present-day treatment being adopted it is found that life can be prolonged only slightly. I am, Sir, yours faithfully,

Portland-place, W., April 29th, 1921. O. LEYTON.

THE HYGIENE OF THE SAILOR.

To the Editor of THE LANCET.

SIR,—In THE LANCET of Jan. 25th, 1921, I have just read "The Hygiene of the Sailor," having previously read all your correspondent's reports in various sections dealing with this matter on some of the larger ships. Having spent six years at sea in 13 different steamship companies as ship surgeon, a few points not touched on may be of interest in connexion with the Mercantile Marine, dealing with not only the sailor, but the surgeon who looks after him. Possibly some of my "points" will reach the man with the "club," for only in this way is improvement to be attained.

First, with regard to the Board of Trade scale of drugs. This is quite antiquated. It only requires a practical man with sea experience in the tropics to discover its inadequacy. My suggestion is that a new scale should be prepared by medical men having sea experience.

Second, appointment of the ship surgeon. No man ought to be appointed till he can produce evidence of his fitness to carry out the duties of this post. This should be judged by (1) having held a post as house surgeon to a hospital; (2) previous shore surgical experience, as in a colliery district; (3) practice on land for a certain period; (4) the holding of a diploma in tropical medicine (if he is intending to travel East, West Indies, or South American ports).

Third, a ship surgeon's bureau. All intending ship surgeons should be compelled to register at a central bureau, which might be in London or Liverpool. At this office information as to medical qualifications, previous sea experience (if any), hospital appointments, and references from at least three independent sources as to moral character and ability would be available. This would to a definite degree eliminate the "wasters."

Fourth, on ships carrying wireless. A list of all surgeons on the various ships carrying wireless should be available by means of a printed slip given to the wireless operator of each ship. This list could easily be brought up to date at the beginning of each month. In this way one doctor could ring up the man he desired in an emergency, as has been done recently, with benefit to surgeon and patient.

Fifth, report as to surgeon's capability. At the conclusion of each voyage a report should be filled in by the commander as to the surgeon's medical capability, conduct, general character, and reliability.

Sixth, testimonials. All testimonials should be only obtained through the central bureau alone, and would in this way be of intrinsic value.

Seventh, inspection of ships prior to sailing. Inspectors should be appointed to visit all ships at the principal ports the day prior to sailing and inspect as in the following manner: (*a*) see if there is adequate supply of water to all baths and latrines throughout the ship; (*b*) inspection of all water carried for drinking purposes; (*c*) inspection of all water-pipes used for sanitary purposes; (*d*) visit all storerooms for food, pantries, cabins, hospital, laundry, butcher's shops, looking into their sanitary condition and fitness for the purpose for which they are supplied; (*e*) overhaul all medical and surgical stores as to their sufficiency and good condition. Three reports should be made—one for the captain, one for the company, and one for the Board of Trade (that for the captain to be available for surgeon's inspection). By this means urgent requirements could be attended to at once, and those of less importance be dealt with on the return to the home port.

During my six years at sea I found that in every case, unless I had carried a small stock of drugs of my own, the supplies were quite inadequate. Testimonials were only given by the company, and were of such a stereotyped style that all real value was lost.

The urgent need of to-day is better accommodation for sailors and firemen. When one has to lay a man up on board ship, where does he go? If it is an urgent case, and one has the hospital, he goes there. In numbers of cases there is either no hospital accommodation or the case is not bad enough for that, and he is told to "go for'ard, and turn in." As Kipling has it, "Lord, what do they understand?" By "they" I mean directors, owners, and the man on top. The turning-in process takes place amidst the "odour" of meals, mixed (!) tobaccos, and the constant chatter of the last man off watch. Then comes the question of treatment. "Oh, anything will do for him." Have you heard this from the steward? No, but I have, and only by putting one's foot down was it possible to get what one ordered, or what the A.B. ought to have. Hygiene on broad lines is splendid, and ventilation a fine thing, but for the Lord's sake give the man in the fo'c'stle a place where he can have some recreation when he comes off watch, and a place where he can smoke without turning his sleeping quarters into a fourth-rate railway smoking compartment.

"We don't treat eyes." This from the superintendent of a large shipping company. And, again—"Oh, well, perhaps we may put one or two things in the ship the next time." This is no exaggeration, but actually occurred to me. "Want the hospital for a sick man, doctor? But I have several cases of literature in it, and what shall I do with them?" I replied, I hope fairly forcibly, that a sick man took precedence—and the hospital was cleared! I could give you many more instances of matters requiring reform, but perhaps the above will suffice.

I am, Sir, yours faithfully,
LEONARD L. BURTON,
Late Surgeon, Pacific R.M.S.P. Co., &c.

Dargaville, N.Z., March 8th, 1921.

⁂ In the Merchant Marine "the urgent need of to-day is better accommodation for sailors and firemen." Dr. Burton, in so saying, reasserts the principle which THE LANCET, knowing how bad were the conditions of life for the crews on board merchant ships, has been impressing on its readers. In the finer, newer ships better conditions are gradually being introduced. A mess-room, apart from the sleeping places, exists in the large Western Ocean Express steamers, for example, and in the *Achilles*. The want of hospitals on board, or "sick-bays" for the crew, is also being met, though medical officers are often faced by hesitations when they seek to have hospital cabins provided, which may mean sudden removal of stores or of unauthorised persons who have been allowed to occupy the available accommodation. Dr. Burton's claims on behalf of medical officers will awaken sympathetic vibrations in the memories of former ship surgeons, and could be fully met by the establishment of a Mercantile Marine Medical Department, composed of medical officers responsible to the Board of Trade first, to the companies afterwards. But this might be unpopular with doctors unwilling to bind themselves permanently to the sea, and the companies would much prefer to have their surgeons in the first place responsible to themselves. Dr. Burton's letter is the outcome of experience. His seventh point, the detailed inspection of a ship before sailing, may seem too far off for hope, but it is carried out on board every transport we have ever heard of, so there can be nothing impossible about its adoption.—ED. L.

MEDICAL COÖPERATION IN SHEFFIELD.

To the Editor of THE LANCET.

SIR,—I should like to add a few supplementary words to the interesting leading article in your issue of April 30th on "Insurance Practice and Research." In the first place, Professor J. B. Leathes holds the post of consulting physiologist, not only at the Royal Infirmary, as stated in your article, but also at the Royal Hospital. At each institution Dr. C. G. Imrie is in charge, under Professor Leathes, of the clinical physiological laboratories. This ensures identical conditions for students attending at either place. As a matter of fact, all the four voluntary hospitals in Sheffield have for some time been united for purposes of clinical teaching under the control of a joint representative committee, and students of the medical faculty are allotted for various periods to each institution. Personally, I believe that this harmonious coöperation of the staffs of the four voluntary hospitals in connexion with the Faculty of Medicine has indirectly been a factor in leading up to the spontaneous and generous action of the Medical Panel Committee which you record. Just as your article shows that the clinician and the laboratory worker have found there is a mutual advantage in coming more closely together, so there have been, latterly, many signs, in this area at any rate, that the gulf which has for so long separated members of hospital staffs from general practitioners may soon be bridged over.

The generous action of the Medical Panel Committee of Sheffield has laid a solid foundation for one pier of the bridge, and with this excellent start I have no doubt whatever that the structure will soon be complete. If such a "rapprochement" between hospital staffs on the one hand and general practitioners on the other can be realised here, there is no obvious reason why it should not be realised elsewhere. When such a thing once comes about it will require but little more to acquire all that is of real importance in the Dawson Committee's findings, and practically at very little cost.

I am, Sir, yours faithfully,

University of Sheffield, May 2nd, 1921. ARTHUR J. HALL.

INTRAVENOUS INJECTION OF STIBENYL IN KALA-AZAR.

To the Editor of THE LANCET.

SIR,—Referring to my paper in THE LANCET of July 24th, 1920, entitled "The Intravenous Use of Acetyl-aminophenyl Salt of Antimony (Stibenyl) in the Treatment of Human Trypanosomiasis and Kala-azar," I have recently read[1] that severe and alarming symptoms have been reported from India following intravenous injection of the organic antimony compounds advocated for the treatment of kala-azar, and with which I obtained remarkable success in one particular case. In my own practice recently severe reactions—vomiting and diarrhœa—have ensued after the injection of 0·4 g. of these compounds.

I venture, therefore, to suggest that further trials should be made with the acetyl-*p*-aminophenyl salts of antimony in doses smaller than those originally advocated in my original paper—say, commencing with doses of 0·05 and 0·1 g. The explanation of this reaction in certain individuals is at present not forthcoming. I am of the opinion that a preparation of antimony, such as the acetyl-*p*-aminophenyl salt, will prove to be more specific for kala-azar than the potassium or sodium tartrates at present in use.

I might add that my name has been used in connexion with advertisements of these antimony compounds in the medical press without my knowledge or consent.—I am, Sir, yours faithfully,

PHILIP MANSON-BAHR.

Weymouth-street, W., April 28th, 1921.

TEACHING OF OBSTETRICS IN INDIA.

To the Editor of THE LANCET.

SIR,—At a recent meeting of the Punjab Legislative Assembly at Lahore, the medical budget was reduced by 4 lakhs of rupees, thereby cutting short the initiation of a scheme to improve the education of Indian students in midwifery. Opinions will no doubt differ, even among those interested in medical education, as to the wisdom or otherwise of the Assembly's action. The teaching of midwifery in India is beset with difficulties, and improvement is urgently needed in the interests of the medical profession. Indian women, like those of other Eastern countries, shrink from male attendance at the time of childbirth. The women of the country are practically all attended by untrained midwives, with a sprinkling of trained midwives and women doctors. Even those who consult male doctors freely enough at other times will not call him in for labour.

Under these circumstances it may be asked, Why train Indian students in midwifery? Because, in the first place, it is necessary if Indian degrees are to be registrable in the United Kingdom. Again, an Indian doctor is frequently called in to serious midwifery cases after all the efforts of the midwife to deliver have failed. He may be called on to deliver a transverse presentation, where the shoulder has been impacted in the pelvis for 48 hours, or a woman whose pelvis is so contracted that two fingers cannot be passed in. Handicapped already by the inconvenience of a small dark room, by lack of skilled help, and by the suspicion and disapproval of the patient's elderly female relatives, woe betide him if he also has no knowledge of midwifery! The Indian doctor is also frequently consulted by his male patients about their female relatives, and has to advise and prescribe for the ailments of pregnancy and the puerperium, even if he never sees the patient. Sometimes his fate is to sit for hours outside a labour room directing a case on the reports of a questionably qualified midwife. He is also sometimes required to attend European women at their confinements, and the fact that he is suspected often to be incompetent to do so is a source of great anxiety to the European community. If Indian medical men had better training and more practical knowledge of obstetrics there can be little doubt that maternity conditions in India, at present deplorable, would improve. At present Indian medical men as a body do little to secure their improvement.

Conditions as regards training in obstetrics differ in different parts of the country. In Madras there is a large Government Maternity Hospital, where thousands of children are delivered annually. Madras has a considerable Eurasian and low-caste population. There is much poverty, and a little money judiciously distributed among the patients has made it possible to organise this fine teaching institution, where both male medical students and midwives receive a good practical training. In Bombay and Calcutta also there are maternity hospitals with a number of cases varying from 1500 to 2000 annually, many of them abnormal. Many of the patients object to be examined by the male students, and so are relegated to the training of midwives.

The scantiness of the clinical material is shown by the fact that the universities require only six cases to be conducted before admission to examination, and to each case four students are allocated. There is nothing corresponding to the system in England by which medical students get a large part of their practical training in the homes of the poor, nor would such a system be possible in India. As one proceeds farther north prejudices become more acute, and in Lucknow and Lahore the labour cases treated in hospital are very few. In Lahore some years ago the medical students struck, and one of the causes of complaint was that students were frequently obliged to go up for the final examination without having seen a single case of labour. The authorities somewhat rashly promised to remedy this, and with that end in view it was proposed to build an up-to-date maternity hospital at Lahore and to offer money rewards to women who would enter it for delivery.

While all must sympathise with the legitimate aspirations of the students and the desire of the Government officials to provide a proper training, there will be many who agree that efforts on the part of Government to break down (in the interests of a small section) a domestic custom so rooted in the hearts of the people would be a dangerous matter. If the scheme were to be tried, it would surely be better to try it on a small scale in an existing ward and to build a special hospital only when the results had shown that practical success was certain to be attained. In the meantime it appears as if better use might be made of the material in the country. At present there is nothing to show whether an Indian medical man has any practical knowledge of midwifery or not. A special Licence of Obstetrics might be instituted in all the universities, open to those who had held resident posts in maternity hospitals or who could produce satisfactory evidence of having attended 100 cases of labour. Post-graduate scholarships might be offered by local governments and arrangements made to allow the holders of these certificates facilities in the larger maternity hospitals. Maternity homes might be opened in connexion with large Eurasian communities, and the holders of the post-graduate scholarships appointed as resident medical officers. In such communities even an externe maternity department might be possible. Holders of the L.O. would be picked men, useful as teachers in medical schools and for appointment to those stations where midwifery is an important item in the work.

---

[1] Mackie: Ind. Med. Gaz., February, 1921, vol. lvi., No. 2, pp. 76–77.

In connexion with the education of the ordinary medical student more attention might well be paid to instruction in operative work with a dummy and preserved fœtus, and less stress laid on vaginal examination and on the witnessing of labour. It is these last items which form an insuperable barrier to most women who might otherwise enter a maternity ward. If a maternity ward were kept private, with an entirely female staff, and the male students were only allowed to enter it twice a week for the clinic, many more women would attend. The students would receive far more knowledge of midwifery from such clinics, which might include a good deal of abdominal examination of waiting cases, than they do from witnessing a case of labour at a distance in the midst of a crowd of men.

One thing is clear. European medical men introducing Western medicine in an Eastern country must be prepared to abandon details only suited to a Western environment, and to adopt new methods of teaching suited to the conditions found in the country if they are to attain the best possible results.

I am, Sir, yours faithfully,

April 4th, 1921. AUDAX.

*** This letter, received from a well-informed source in India, may be taken as supplementing the passage in our leading article of April 9th, in which we expressed the hope that the difficulty in obtaining sufficient obstetric experience for Indian students would not prove insurmountable.—ED. L.

"LIFE AFTER DEATH."

To the Editor of THE LANCET.

SIR,—The adjustment between concrete and abstract knowledge is ever taking place, and sometimes it is sufficiently active to create some sort of disturbance in our mental outlook. When this affects our lay population, as the fashionable "inquiry" into spiritualism is now doing—an aftermath of war and suffering—we become concerned as to the national sanity; when it appears in our scientific press, as the annotation on Life After Death in the issue of THE LANCET of April 23rd shows, we are made to realise that the purported happenings of spiritualism are left to only a few scientific men, and mainly to the mercies of laymen who do not understand the little we ourselves know of the subliminal or unconscious mind. Thus we are reminded that we are guilty of neglecting this means of studying the unconscious mind.

That these spiritualistic phenomena are most probably the reactions of the unconscious mind, capable itself of error and misdirection, most men versed in psychological findings will agree. But yet, as the atomic nucleus remains unknown in all but its mass and its radio-activity to the physicist, so does the unconscious remain equally unknown to the physician, who only knows those mental "radiations" manifested in his patient's dreams and in the storms of mental disease. The whole of the latent content of the mind remains, like the structure of the atomic nucleus, unknown. It seems, therefore, that the interest of these phenomena lies in the aspect they present in the study of the unconscious mind, and investigation should not be left to a small scientific group which may be in error, far less to lay amateurs, who are more liable still to erroneous deductions. The student of the unconscious must remember that certain of its units of memory, the "images lying dormant" in the unconscious,[1] or the bases of the pyramids of memory complexes (Freud), are most apt to be revived in, and taken up from, the sitter by a psychic medium during certain mental states, and that it is the demonstration of this knowledge acquired by the medium that is so liable to startle, convince, and lead astray anyone who sets himself the task to unravel the problem.

It has been stated by responsible men that the unconscious can be definitely excluded as an explanation of these manifestations; but this seems illogical: for it is impossible to exclude an entity as the cause of an effect while having only a limited knowledge of that entity, and this is more so in mental physics than elsewhere. For all we know the phenomena of "materialisation" may be the result of conscious or unconscious falsification on the part of the medium. On the other hand, it must be admitted that all our knowledge of reality is based on instinctive pre-knowledge—a property of the unconscious; further, we know that the events that follow the formation of a retinal image in our fields of vision and their relations to the objects that cause the stimulus, are subjected to a process of unconscious coördination so that we do not get an inverted and diplopic view of the external world. It seems that even our conception of external reality is guided and coördinated by the unconscious.

I am, Sir, yours faithfully,

April 30th, 1921. M.D.

THE DIET OF THE WEANLING.

To the Editor of THE LANCET.

SIR,—The diet of the weanling is a subject of immense importance, but, unhappily, one concerning which disastrous ignorance prevails in this country.

Reference has been made in your correspondence columns concerning the amount of milk the weanling requires. Sir, the weanling requires no milk whatever. It amazes me that this elemental truth is not taught in our medical schools. Pure milk, whether from the cow, goat, mare, or ass, is a good enough food in moderation from the time of weaning to the end of the chapter, but—it is not essential.

Another truth all but wholly overlooked in this country: the diet of the growing human from the time of weaning onwards should be such as shall enable the jaws to grow sufficiently to allow the whole 32 permanent teeth to take up their proper position without jamming. So to feed our youth as not to allow the masticatory apparatus to develop normally is to rob them of their birthright, of what, indeed, is more truly their birthright than any gift which can be bequeathed by testament. A due appreciation of this truth would do more to improve the health of the community than all the team-work carried on at our medical centres is likely to achieve in the next half-century. I say this while fully appreciating the good which is likely to accrue from this movement.

So absorbed are we in the investigation of the obscure that we are in some danger of overlooking the glaringly obvious.

I am, Sir, yours faithfully,

Wimpole-street, W., April 30th, 1921. HARRY CAMPBELL.

---

[1] Cf. Jung: Collected Papers on Anal. Psych., 2nd ed., pp. 374, 410.

LIVERPOOL MATERNITY HOSPITAL.—The annual meeting of this hospital was held on April 28th in the Town Hall, the Lord Mayor presiding. The annual report showed an increase in the number of patients, the hospital having been full the whole year; many cases had to be refused for lack of accommodation. During the year 27 women medical students and 68 men students took their midwifery practice at the hospital. Eighty-two pupil midwives took the prescribed course of training, and 77 of these were successful in passing the examination of the Central Midwives Board. Sir William Hartley's generous offer of £25,000 and a site for a new hospital has been accepted, and the Board is about to raise additional funds to set about building this hospital. On the year's workings there is a deficit of £1044, and the committee is anxious for increased contributions.

Obituary.

HENRY EDWARD JULER, F.R.C.S. ENG.,

CONSULTING OPHTHALMIC SURGEON, ST. MARY'S HOSPITAL.

Mr. Henry Juler, whose death on April 23rd, from pneumonia, was recorded last week, was the son of Dr. H. C. Juler, a Suffolk practitioner, and received his medical education at St. Mary's Hospital, London, where he held in succession the appointments of demonstrator of anatomy, medical registrar, and medical superintendent. After post-graduate study in Paris and Berlin, he decided to devote himself to ophthalmic work, and was appointed clinical assistant to the Royal London Ophthalmic Hospital. At the same time he started practice in Wimpole-street, with the usual early struggles, which ultimately gave place to a very large practice in Cavendish-square. On his appointment to the staff of the Royal Westminster Ophthalmic Hospital, where was at that time abundant clinical material but no systematic teaching, he set himself with customary energy to remedy this and, with the assistance of his colleagues, laid the foundation of a successful school of ophthalmology. In 1884 he was appointed to the ophthalmic staff of St. Mary's Hospital as junior to Sir Anderson Critchett, whom he subsequently succeeded. It was then that he became deeply interested in the pathological side of ophthalmology, many of the specimens prepared by him being now in the museum of the Royal College of Surgeons of England.

Juler was not a prolific writer, but his "Handbook of Ophthalmic Science and Practice" went through three editions and is still widely read here and in America. His Harveian lectures on Syphilitic Diseases of the Eye and its Appendages, delivered in December, 1897, were a judicious blend of accurate clinical and pathological observation, and his occasional contributions to medical societies were as much concerned with the basis of disease as with its manifestations. The same attitude is apparent in an introductory address to students delivered at St. Mary's Hospital in 1893.

Two of Mr. Juler's friends and contemporaries have sent us an intimate account of his life and work, which may be quoted:—

> Juler was a man of untiring energy and enthusiasm, both in his work and in his recreation. He was a familiar equestrian figure in Hyde Park in the early morning, educating his children in horsemanship. He rode fearlessly, not without occasional accidents, and his cheeriness of disposition carried others with him in sports and pastimes. His operative skill and dexterity were accompanied by a sympathetic consideration for the patient's trouble which made him very popular as a consultant. Early in the war he lost his younger son, who was in the first Expeditionary Force, a blow from which he never quite recovered. Previous to this he had resigned his hospital appointments, but returned to work at the Westminster Ophthalmic Hospital during the period of stress.

For the last two years he had been gradually retiring from practice, his elder son succeeding to his work. His loss is felt by a large circle of patients and friends, and much sympathy will be extended to his widow, surviving son, and three daughters.

DEATH OF DR. ARTHUR F. DOBBS, OF ATHLONE.—Great regret is felt both in his own neighbourhood and in Dublin at the death of Dr. Arthur Dobbs, one of the leading practitioners of the Irish midlands. He had been overworked for years past, but had remained at his post. On April 20th he entered on his duties as usual, but felt ill in the course of the morning, and died in the afternoon. For many years he had practised in Athlone, and was held in respect and affection by all classes of the community. With a deep sense of the responsibility of professional work, he not only attended to his patients with the most scrupulous care, but as time permitted he kept in touch with modern knowledge by constant study and by post-graduate courses.

DEATH OF DR. F. H. PICKIN.—Frederick Harold Pickin, M.R.C.S. Eng., late Captain, R.A.M.C., who died suddenly on his birthday, April 28th, at the age of 45, received his medical education at the London Hospital and at Bristol, where he held resident appointments at the General Hospital. After qualifying in 1903, he was appointed assistant surgeon at All Saints Hospital, London, where his interest in urinary diseases began. His contributions to medical literature included a paper on A Routine Method of Examination in Gonorrhœa in the Male as a Guide to Treatment, which appeared in THE LANCET, 1913, i., 76. At the time of his death he was hon. surgeon to out-patients at St. Paul's Hospital for Skin and Genito-urinary Diseases.

THE LATE DR. W. H. WOODGER.—William Hawkley Woodger, who died suddenly on April 23rd at his residence in Newcastle-on-Tyne, was a well-known medical practitioner in that city. Educated at the University of Durham, he obtained the triple Scottish qualification in 1905, and immediately entered into general practice at Newcastle. During the war he was employed on active service in Egypt, where he contracted malaria, from which he never fully recovered. He leaves a widow and three sons.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surgeon-Lieutenants to be Surgeon Lieutenant-Commanders: J. O. Sinclair and H. L. P. Peregrine.

Surg. Lieut. (D.) A. T. Dally to be Surgeon Lieutenant-Commander (D.).

ROYAL ARMY MEDICAL CORPS.

Capt. E. Catford relinquishes the acting rank of Major.

Temp. Capt. G. J. McGorty to be Captain.

Lieutenants (temporary Captains) to be Captains: A. R. Barlas and E. N. P. Martland.

E. C. Fawcett, late temporary Captain, to be temporary Captain.

Officers relinquishing their commissions: Temp. Major R. A. Beaver (retains the rank of Major). Temp. Capt. F. L. Dickson. Temporary Captains retaining the rank of Captain: J. Joule, W. Spiteri, G. Fleming, E. Bryceson, H. R. McNair, J. Crean, E. S. Joske, T. H. Jackson, and W. D. Perry. Temporary Lieutenants retaining the rank of Lieutenant: S. E. Price and W. A. Byrn.

ARMY DENTAL CORPS.

To be Majors: Temp. Majors W. T. Finlayson (from R.A.M.C.) and A. K. Macdonald (Dental Surgeon, from Special List), and Temp. Capt. (acting Major) J. A. Seymour (Dental Surgeon, from General List). Dental Surgeons to be Captains: Temp. Capts. R. H. Bebb (from General List), A. B. W. Rust (from General List), E. Smith (from General List), A. B. Austin (from Special List), R. H. Mills (from Special List), and E. R. Saul (from Special List); A. F. Salsbury (from temporary Major, Special List).

OVERSEAS FORCES.

South African Medical Corps.—Temp. Capt. G. S. Coghlan relinquishes his commission on completion of service, and retains the rank of Captain.

TERRITORIAL FORCE.

Capt. (acting Major) E. Osborne relinquishes the acting rank of Major on ceasing to be specially employed.

Capt. F. D. Marsh, from 1st Southern General Hospital, to be Captain.

D. J. Davies to be Lieutenant.

DEFENCE FORCE.

To be temporary Majors: C. Walker, B. Addenbrooke, C. B. Baxter, S. J. C. Holden, and L. R. Colledge. To be temporary *Captains*: A. Morris, C. H. Comerford, J. Morham, W. George, A. C. H. McCullagh, S. J. Clegg, B. E. A. Batt, H. Wilson, W. Tresawna, J. Grant-Morris, O. H. Mavor, J. A. Stenhouse, H. L. Garson, A. Walker, H. K. Ward, E. Scott, and F. J. Morris. To be temporary Lieutenant: A. Fisher.

4th London (D.F.) Field Ambulance:—To be temporary Lieutenant: C. C. Coghlan.

5th London (D.F.) Field Ambulance:—To be temporary Major: E. T. H. Lea.

6th London (D.F.) Field Ambulance:—To be temporary Captains: J. Rowland and J. O. Thomas. To be temporary Lieutenant: L. Samuels.

1st East Anglian Field Ambulance:—To be temporary Lieutenant-Colonel: H. F. Everett. To be temporary Captains: W. J. Rice, H. V. Walsh, C. S. Stadden, and W. S. Forbes.

Sanitary Section:—To be temporary Captain: G. T. Stewart.

1st South Midland Field Ambulance:—To be temporary Lieutenant-Colonel: W. Stobie.

3rd (Home Counties) Field Ambulance (D.F.):—To be temporary Lieutenant-Colonel:—H. G. G. Mackenzie.

2nd (West Lancs.) Field Ambulance (D.F.):—To be temporary Lieutenant-Colonel: G. C. E. Simpson.

3rd (West Lancs.) Field Ambulance (D.F.):—To be temporary Major: A. J. D. Riddett.

2nd West Riding Field Ambulance (D.F.):—To be temporary Major: T. B. Kenworthy. To be temporary Captain: D. F. Dobson.

3rd West Riding Field Ambulance (D.F.):—To be temporary Major: E. F. Skinner. To be temporary Captains: R. A. Stark, W. T. D. Mart, and R. E. Pleasance.

2nd (Wessex) Field Ambulance (D.F.):—To be temporary Lieutenant-Colonel: C. M. Kennedy.

3rd (Wessex) Field Ambulance (D.F.):—To be temporary Lieutenant-Colonel: E. Alderson.

ROYAL AIR FORCE.

The undermentioned are granted temporary commissions as Flight Lieutenants: C. P. Barber, J. F. P. Gallagher, H. C. E. Quin.

Capt. G. M. Mellor is transferred to the unemployed list.

Parliamentary Intelligence.

HOUSE OF LORDS.

TUESDAY, MAY 3RD.

PUBLIC HEALTH (TUBERCULOSIS) BILL.

THE Earl of ONSLOW (Parliamentary Secretary of the Ministry of Health), in moving the second reading of the Public Health (Tuberculosis) Bill, said that the deaths from tuberculosis during the past six years were as follows:—1915, 54,295; 1916, 53,858; 1917, 55,734; 1918, 58,073; 1919, 46,312; 1920, 42,545. The drop in the figures in the last two years was mainly due to the valuable services rendered by the county councils in combating disease, and afforded proof of the immense gain to the nation through their work. The number of beds provided for tuberculosis patients by the local authorities and voluntary institutions had increased since 1912 from 4300 to 17,447.

Lord STRACHIE said that, on the whole, the county councils were fairly satisfied with the Bill, and were obliged to the Ministry of Health for the way in which they had considered many amendments they had suggested. They approached the Bill in no hostile spirit. The feeling at the meeting of the County Councils Association was that as the Bill made sanatorium treatment compulsory on the county councils the obligation to pay for the same should also be compulsory.

The Earl of ONSLOW said that the Government had promised to find £300,000 to reimburse the councils plus a further grant this year of £1,000,000. It was the fixed and firm policy of the Government to continue this institutional treatment of tuberculosis.

Lord SYDENHAM asked whether the figures mentioned by the noble lord represented the maximum annual expenditure under this bill.

The Earl of ONSLOW said that the block grant might be regarded as final, but the £200,000 depended on the amount that the councils spent on the approved schemes each year.

Lord HARRIS protested against the enormous charge which was being thrown on the rates for this purpose. The treatment of tuberculous people was a national object and their cure was a national advantage. Why, then, should such a very large proportion of the cost be thrown on the rates? Why should it not be 25 per cent. on the rates and 75 per cent. on the Exchequer?

The Bill was read a second time.

HOUSE OF COMMONS.

THURSDAY, APRIL 28TH.

Grouping of Medical Appeal Boards.

Mr. WATERSON asked the Minister of Pensions whether there had been any joining together of medical appeal boards; if so, for what purpose; and under what powers such had been done.—Mr. MACPHERSON replied: The answer to the first part of the question is in the negative. Perhaps my honourable friend has in mind an administrative arrangement by which, in certain large areas, a number of boards may be grouped for supervision under one Deputy Commissioner of Medical Services, each board, however, retaining its own chairman.

University Students and Defence Force.

Mr. RENDALL asked the Secretary for War what action he intended taking on the letter received from Sir I. Owen, Vice-Chancellor of the University of Bristol, which pointed out the importance of university students being released from the Defence Force at the earliest possible moment.—Sir CHARLES OMAN asked the Secretary for War whether he would take measures to secure the prompt demobilisation of those university students who were still retained by their colonels in the battalions of the Defence Force, when the large majority of such persons had been granted leave to return to their studies and examinations, as cases of great hardship were being reported by university authorities.—Sir L. WORTHINGTON-EVANS replied: It is not possible to give leave to students from the Defence Force without at the same time giving leave to others who may desire it on urgent grounds. It is hoped, however, that the present negotiations will lead to a speedy settlement, when steps will be taken to demobilise the Defence Force.

Medical Equipment of Auxiliary Division, R.I.C.

Lieutenant-Colonel WALTER GUINNESS asked the Chief Secretary to the Lord Lieutenant of Ireland whether the Auxiliary Division, Royal Irish Constabulary, were still entirely without medical staff or ambulances; and whether, in view of the very dangerous work and heavy casualties which their units were now sustaining, he would consult the Director of Medical Services as to the advisability of attaching to each company one motor ambulance, one medical non-commissioned officer, and two medical orderlies.—Sir H. GREENWOOD replied: As stated by my right honourable friend, the Attorney-General (Mr. Henry), in reply to a question on this subject on April 14th, the Auxiliary Division is not provided with its own special medical transport, but ambulances and other necessaries of medical equipment are borrowed from the Regular Forces as and when required. I have inquired into the working of this arrangement, and am assured that it is found to answer satisfactorily, as the whereabouts of neighbouring military stations are well known and can be communicated with easily in the event of casualties occurring.

Supervision of Private Vaccine Farms.

Mr. HAYDAY asked the Minister of Agriculture whether his department exercised any supervision over the private vaccine farms in this country in which vaccine lymph was manufactured, having regard to the fact that at least two outbreaks of foot-and-mouth disease in the United States of America had been attributed by the authorities to the use of contaminated vaccine lymph on private vaccine farms.—Sir. A. BOSCAWEN replied: The Ministry exercises no supervision or control over private vaccine farms in this country in which vaccine lymph is manufactured. I may add that the Ministry has inquired into hundreds of outbreaks of foot-and-mouth disease in this country since the report from the United States of America was published, but in no case has any evidence been obtained that foot-and-mouth disease has ever been introduced into Great Britain through the medium of vaccine lymph.

Proposed Reduction of Government Medical Staff.

Major Sir KEITH FRASER asked the Minister of Health what necessity there was for having increased the number of medical men on the public health staff in the direct service of the Government from 39, who performed the functions under the Local Government Board in 1914, to 100, at present employed by the Ministry of Health, at an annual cost which was increased from £26,871 15*s.* 9*d.* in 1914 to £130,630 3*s.* in 1920; and whether he proposed to take any steps to reduce the numbers and cost.—Sir A. MOND replied: I am inquiring into the functions and numbers of the medical branch of the Ministry, and pending the result of the inquiries have given instructions that no vacancies arising in the medical branch are to be filled.

Educational Food Leaflet.

Colonel Sir ARTHUR HOLBROOK asked the Minister of Health when it was proposed to issue the educational food leaflet, the draft of which was submitted early in March, with a memorial on this subject from medical, scientific, health, and other associations; and would he deal with the matter as one of urgent importance, having regard to the present general distress and the consequent necessity for disseminating knowledge of healthy, nourishing, and economical foods.—Sir A. MOND replied: The matter is receiving attention and I will see whether any useful purpose can be served by issuing any such pamphlet.

Protection against Small-pox.

Mr. FREDERICK GREEN asked the Minister of Health, in view of the statement contained on page 219 of the annual report of the chief medical officer of the Ministry for the year 1919-20 that cases of small-pox did not occur after recent successful re-vaccination, how recent re-vaccination should be in order to be absolutely protective; and what were the characteristics represented by the word successful.—Sir A. MOND replied: I am advised that the protection against small-pox infection by efficient vaccination is practically absolute during the early years following the operation and that in the great majority of cases the protection remains effective up to the tenth or eleventh year after vaccination. The evidence of successful vaccination is the production at the seat of inoculation of the characteristic lesions followed by well-defined marks.

MONDAY, MAY 2ND.

The Spahlinger Treatment.

Mr. HIGHAM asked the Prime Minister whether he would consider the advisability of appointing a commission to investigate at once the merits of the Spahlinger treatment for consumption, particularly in view of the fact that 18 persons were treated in England with this serum in 1913-14 when they were in the third degree of consumption, and to-day these persons were well and able to carry on their former occupations; and whether, in view of this fact and also that 40,000 people died of consumption annually in this country, he would consider it desirable to exhaust every means in his power to secure the Spahlinger treatment for this country so that it might be available to all people suffering from consumption in any of its stages.—Sir A. MOND (Minister of Health) replied: I may remind my honourable friend that the question of the merits of the Spahlinger treatment for consumption have been under consideration by the responsible medical authorities in this country since 1914; and during the last few months the Ministry of Health, following their usual practice of investigating the efficacy of all new methods of treatment for tuberculosis which are brought forward, have given further special attention to the matter at the particular request of Mr. Spahlinger. The difficulty in the case is, however, that the serum itself and reliable details of the clinical evidence in support of its use are not forthcoming. An undertaking has, however, been given that when supplies of this serum become available for independent and scientific investigation in this country the Ministry of Health will facilitate an exhaustive examination of its efficacy. The appointment of a commission as suggested by my honourable friend would not therefore appear to be of any advantage at the present time. I think it desirable to emphasise that in the opinion of my medical advisers there is not yet available a sufficient body of evidence to justify the claims made for this treatment.

Cost of the Ministry of Health.

Mr. MILLS asked the Minister of Health if he would submit a return showing the total expenditure defrayed out of national funds in respect of each of the administrative sections under the control of his department during each of the last two completed financial years, and also the estimated similar expenditure in respect of the current financial year.—Sir A. MOND replied: I am not quite clear what the honourable Member has in mind. If, as I assume to be the case, he refers to grants made by the department out of voted moneys towards the cost of housing, national health, insurance, and miscellaneous health services, the information is as follows:—

	Expenditure.		Estimated expenditure.
	1919–20	1920–21	1921–22
	£	£	£
Housing	24,109	3,145,888	11,000,000
National Health Services	6,596,436	7,713,704	8,500,000
Miscellaneous „ „	777,142	2,451,059	3,000,000

Indian Medical Service Appeals.

Major GLYN asked the Secretary for India whether British officers of the Indian Medical Service had any right of appeal if the contention was upheld that such officers had no right of appeal under Section 42 of the Army Act, and with special reference to the notification in the *London Gazette* of March 15th, p. 2099; and, if so, by what procedure they could appeal.—Mr. MONTAGU replied: I am advised that officers of the Indian Medical Service have no right of appeal under Section 42 of the Army Act, but have a right of appeal to the Governor-General under Section 180 (2) (d) of that Act. If dissatisfied with his orders they may then appeal to the Secretary of State for India, and through him to H.M. the King.

Small-pox and Vaccination.

Mr. ROBERT YOUNG asked the Minister of Health if his attention had been called to the following figures relating to the cases of small-pox notified in 1919—namely, 294—as shown on pages 34 and 39 of the First Annual Report of the Minister of Health, and pages 27 and 241 of the Annual Report of the Chief Medical Officer for 1919-20; 288, as shown on page 215 of the last-named Report; and 361, as shown on page lxviii. of the Registrar-General's Annual Report; if he would state the reason for these differences and say what was the total number of cases notified or discovered in 1919, and how many of those cases occurred amongst each of the civilian, military, and naval sections of the population, and how many in port sanitary districts; and how many deaths occurred in each of these sections.—Sir A. MOND replied: The figure 288 shown on page 215 of the Annual Report of the Chief Medical Officer of the Ministry for 1919-20 is the total number of cases of small-pox notified under the Infections Diseases (Notification) Act during 1919. Twenty-three of these cases were afterwards withdrawn on the ground of incorrect notification, and 29 cases were discovered in the civilian population which had not been notified. The figure 294 shown on pages 34 and 39 of the first Annual Report of the Minister of Health, and on pages 27 and 241 of the Annual Report of the Chief Medical Officer, which is arrived at by adding 29 to the figure 288 and deducting 23 therefrom, is the actual number of cases of small-pox occurring in the civilian population during 1919. Of these cases 38 occurred in port sanitary districts. In addition, 13 military and 4 naval cases occurred in this country, and 50 service men arrived in this country convalescent from small-pox incurred abroad. The figure 361 shown on page lxviii. of the Registrar-General's Annual Report is arrived at by adding these 50 cases to the total number of civilian, naval, and military cases which occurred in this country. The number of deaths was 25 in the civilian, 4 in the military, and none in the naval sections of the population.

Mr. LUNN asked the Minister of Health how many deaths from small-pox had occurred amongst children under 5 years of age in each year since the passing of the Vaccination Act, 1907; and how many deaths of children under 5 years of age in each of those years had been certified by the doctor in attendance as having been caused by, or associated with, the operation of vaccination.—Sir A. MOND replied: The particulars asked for, according to the Registrar-General's Returns so far as England and Wales are concerned, are as shown in the following table:—

Deaths of Children Under 5 Years of Age.

Year.	Small-pox.	Vaccination.*	Year.	Small-pox.	Vaccination.*
1908	1	13	1915	2	7
1909	1	11	1916	3	2
1910	2	8	1917	—	6
1911	5	15	1918	—	3
1912	2	9	1919	2	6
1913	1	7	1920	5	10
1914	1	5			

* Certified by doctor to have been caused by, or associated with, vaccination.

Mr. CHARLES WHITE asked the Secretary for Scotland how many deaths from small-pox had occurred in Scotland amongst children under 5 years of age in each year since the passing of the Vaccination Act, 1907; and how many deaths of children under 5 years of age in each year had been certified by the doctor in attendance as having been caused by, or associated with, the operation of vaccination.—Mr. MUNRO replied: The answer to the first part of the question is 28, of whom 27 were unvaccinated and 1 vaccinated. The answer to the last part of the question is 6.

UNIVERSITY OF CAMBRIDGE.—At a Congregation held on April 29th the following degrees were conferred:—

M.D.—C. R. Taylor, Caius.
M.B. and B.Ch.—P. F. Bishop, Clare.
M.B.—E. H. H. Granger, Clare.
B.Ch.—H. B. Dodwell, Emmanuel.

UNIVERSITY OF LONDON: *Election of Senate.*—The semi-general election has resulted in the appointment of the following medical men as members of the Senate for the period 1921-25: Sir Wilmot Herringham (R.C.P. Lond.), Mr. Raymond Johnson (R.C.S. Eng.), Mr. H. J. Waring (Faculty of Medicine), Dr. G. N. Pitt (City and Guilds Institute), and Dr. E. G. Graham Little (Convocation).

The Graduation Dinner.—On account of the present industrial crisis and the necessity for saving coal and light, the University authorities were compelled to cancel the graduation dinner fixed for yesterday evening, Thursday, May 5th. In order to mitigate the disappointment which this decision will necessarily cause, the Prince of Wales consented to attend a reception at the Guildhall during the afternoon, when the manuscript given by the graduates and undergraduates of the University was presented to His Royal Highness.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—An ordinary Comitia of the College was held on April 28th, Sir Norman Moore, the President, being in the chair. The following were admitted to the *Membership* of the College: Dr. James B. Alexander, Dr. George Ashton, Dr. Percy S. Blaker, Dr. John A. M. Bligh, Dr. Loswel I. B. Braun, Dr. Ernest A. Broughton, Dr. George S. Buchanan, Dr. Ruth E. Conway, Dr. Arthur J. Eagleton, Dr. Ernest G. Ffrench, Dr. Charles B. Heald, Dr. Godfrey T. Hebert, Dr. Arthur H. Holmes, Dr. Alice M. Hutchison, Dr. Henry W. Jones, Dr. John W. Linnell, Dr. Charles C. Okell, Dr. Donald H. Paterson, Dr. Miles K. Robertson, Dr. James A. Shorten, Dr. James C. Spence, Dr. Ernest B. Verney, and Dr. Cecil C. Worster-Drought.—Licences to practise Physic were granted to 103 candidates who had passed the required examinations and conformed to the by-laws and regulations.

Diplomas in Tropical Medicine and Hygiene were granted, jointly with the Royal College of Surgeons, to the following candidates: John O. Beven, Francis Xavier Costello, Andrew Crawford, John P. de Silva, William M. Howells, Annie M. Mackay, Charles T. Maitland, Mary Martin, Malcolm Morrison, Parasurama Parthasarathy, Robert A. W. Proctor, Benoy Kumar Ray, Henry E. S. Richards, Mona M. Ross, Chuni Lal Sahni, Douglas S. Scott, Jacob Ségal, Lolitmohan Sen, Pran Nath Seth, Robert G. Simpson, and Herbert Smith.

The following were elected to the *Fellowship* on the nomination of the Council: Dr. Charles O. Hawthorne, Dr. Arthur J. Cleveland, Dr. Charles H. Melland, Dr. Joseph G. Emanuel, Dr. Frank H. Jacob, Dr. Alfred E. Barnes, Dr. John P. Hedley, Dr. James A. Torrens, Dr. Alfred J. Clark, Dr. Anthony Feiling, Dr. Robert H. Steen, Dr. Charles McMoran Wilson, Dr. George E. S. Ward, and Dr. John B. Leathes.

Sir Norman Moore was unanimously re-elected a Representative of the College on the General Medical Council, and Sir Wilmot Herringham was re-elected a Representative of the College on the Senate of the University of London.—The following schools were recognised for instruction in chemistry and physics: Christ's Hospital, Horsham; Handsworth Technical School, Birmingham; and Ipswich High School for Girls. Leicester Municipal Technical School was recognised for Instruction in Biology, and the South London Hospital for Women was recognised for the gynæcological clerkship. It was resolved to admit licentiates in medicine and surgery of King Edward VII. Hospital Medical School, Singapore, to the Second and Final Examinations.—After some formal College business had been transacted the President dissolved the Comitia.

ROYAL COLLEGES OF PHYSICIANS OF LONDON AND SURGEONS OF ENGLAND.—At the Final Examination of the Conjoint Examining Board, held from April 5th to 25th, the following candidates were approved in the under-mentioned subjects, but are not eligible for diplomas:—

Medicine.—S. Adler and D. R. Ainsworth, Manchester; W. Beaumont, London; Lorna Phœbe Brown, Univ. Coll.; E. M. Burrell, Cambridge and St. Thomas's; Christabel L. M. Charlesworth, King's Coll.; J. C. Churcher, St. Thomas's; C. S. Cloake and E. C. T. Clouston, London; C. L. Cottle, Glasgow and Liverpool; Nancy M. Coutts, Royal Free; P. T. Davidson, Middlesex; H. K. Denham, Oxford and St. Bart.'s; E. C. Dodds, Middlesex; T. W. K. Dunscombe, Durham; E. S. Etheridge, Univ. Coll.; J. C. Evans, London; H. Finklestone, Sheffield; Betty Fletcher, St. Mary's; J. Franks, London; E. St. C. Gainer, Middlesex; L. D. Gorton, Birmingham; A. Gullertein, London; A. H. Hall, Birmingham and London; Marjorie C. Hawkins, Westminster; A. D. Hepburn, Cardiff and Westminster; R. J. Hodgkinson, Guy's; Marjorie Browning Hubert, St. Mary's; A. Ismail, Dublin; E. R. Jagger, Manchester; Erna Henrietta Jebens, Royal Free; D. J. Jones, Westminster; A. M. Khaleel, Middlesex; A. Kotbi, St. Mary's; W. E. Lloyd and D. M. Lloyd-Jones, St. Bart.'s; D. McClean, St. Thomas's; J. F. C. McColl, Liverpool; A. Maude, Manchester; Enid M. Moore, St. Mary's; Rose Moss, Charing Cross; R. E. Murray, Calcutta; E. R. D. Nagel, St. Thomas's; V. L. Parmar, King's Coll.; V. D. Pennefather, London; B. T. Richards, Birmingham; W. G. Roberts, Liverpool; A. Robertson, Guy's; T. Seschachalam, Madras and London; H. Shannon, St. Bart.'s; A. H. Shelswell, Guy's; S. S. Shri-Kent, Liverpool; S. R. Simaika, St. Bart.'s; H. K. Snell, King's Coll.; A. D. Soares, Bombay; A. Sourasky, Leeds; Dorothy Mary Stewart, St. Mary's; L. W. Studdy, Durham; Muriel Amy Sutton, Univ. Coll.; J. G. Tait, Edinburgh; Wenefride Thompson, St. Mary's; Doris Lyne Veale, Royal Free; J. G. Walker, Charing Cross; L. R. A. Wells, Guy's; E. T. Wright, St. Mary's; and J. E. Wright, Guy's.

Midwifery.—N. A. Aiengar, Guy's; O. A. Akjaly, Liverpool; V. H. Barker, London; Marjorie M. S. Bartlett, St. George's; A. W. Brown, Cambridge and St. Bart.'s; Lorna Phœbe Brown, Univ. Coll.; Margaret H. Burrows and Linda Catmur, London; R. B. Chandrachud, Guy's; Christabel L. M. Charlesworth, King's Coll.; A. J. Chiappa, Middlesex; J. C. Churcher, St. Thomas's; W. E. R. Coad, Toronto; W. E. Cody, St. Bart.'s; Muriel Coope, Manchester; J. M. Craig, Dundee and St. Mary's; G. C. W. Curson, Guy's; K. A. Darukhanawala, Middlesex; J. B. Devine, King's Coll.; J. H. Doggart, Cambridge and St. Thomas's; H. S. Drabble, Sheffield; Winifred M. Edghill, Manchester; Doris Emery, Royal Free; F. T. Evans, St. Bart.'s; A. Farid, Guy's; W. E. Farnham, Birmingham; Ena Dorothy Foster, St. Mary's; N. Gallant, London; G. L. Gatoly, Liverpool; Kate Glyn-Jones, London; L. D. Gorton, Birmingham; E. F. Griffith, St. Mary's; F. Guiver, London; C. M. Gwillim, St. Bart.'s; J. F. Hackwood, St. Thomas's; T. H. J. Hargreaves, Charing Cross; Muriel M. Harris, King's Coll.; S. G. Harrison, St. Bart.'s; S. Hartley, St. Thomas's; I. Hipshon, Leeds; R. V. Hudson, Middlesex; A. B. Isaacs, St. Thomas's; Erna Henrietta Jebens, Royal Free and St. Mary's; A. O. Jones, Liverpool; R. G. Karn, Univ. Coll.; Kathleen H. B. King, Royal Free; G. B. Kirkland, Guy's; D. H. J. Kirton, Birmingham; Emilia B. M. Krause, London; D. M. Lloyd-Jones, St. Bart.'s; Eva Lombard, Geneva; Geraldine N. Longford and Muriel J. Lough, St. Mary's; F. Q. McKeown, Liverpool; Frances Mary Margerison, Charing Cross; A. Mitchell, King's Coll.; Enid M. Moore, St. Mary's; J. N. Morris, King's Coll.; D. C. Muir, Middlesex; J. Ness-Walker and W. H. Nettlefield, St. Bart.'s; J. B. Oldham, Liverpool; A. E. Parkes, St. Bart.'s; V. L. Parmar, King's Coll.; D. H. Patey, Middlesex; V. D. Pennefather and Ruth E. Pilgrim, London; Mary W. Pitt-Lewis, St. Mary's; J. H. Porter, Univ. Coll.; Enid M. Powell, Charing Cross; F. L. Rayner, Guy's; J. G. Reed, St. Thomas's; P. D. Richards, St. Bart.'s; W. G. Roberts, Liverpool; A. R. Verwey, Leiden and St. Bart.'s; and W. H. Williams, Charing Cross.

RONTGEN SOCIETY.—The Manchester meeting of this Society, announced for May 6th and 7th, was postponed owing to the coal strike.

POST-GRADUATE COURSE OF INSTRUCTION IN TREATMENT OF VENEREAL DISEASES.—A two weeks' course for qualified medical women, arranged by the London (R.F.H.) School of Medicine for Women, the Royal Free Hospital, the Elizabeth Garrett Anderson Hospital, and the London Lock Hospital, will begin on Tuesday, May 17th, at 10 A.M., with an introductory lecture on "Some Aspects of the Venereal Problem," by Mr. J. E. R. McDonagh, at 8, Hunter-street, London, W.C. The Ministry of Health recognises attendance at this course as qualifying the medical practitioner who has pursued it to receive free drugs for treatment. The course will consist of visits to and demonstrations in various departments of the three hospitals under the direction of Miss Margaret Basden, Dr. Margaret Rorke, Mr. Charles Gibbs, Dr. Ruth Balmer, Dr. David Thomson, Mr. J. Ernest Lane, Mr. J. E. R. McDonagh, and Mr. J. Johnston Abraham. Fees for the full course, £5 5s., payable on entry. The library, refectory, and common rooms at the London (R.F.H.) School of Medicine for Women are available for use by the post-graduate students attending the course. Qualified medical women wishing to attend are asked to send in their names not less than seven days before the course begins to Miss L. Brooks, at 8, Hunter-street, London, W.C.1.

The King has sanctioned the promotion of Lieutenant-Colonel L. N. Robinson, C.B.E., R.A.M.C., to Knight of Grace, and the appointment of Captain E. B. Allnutt, M.C., R.A.M.C., to Esquire in the Order of St. John of Jerusalem in England.

Guild of Blind Gardeners.—A project for the useful and healthy employment of the labours of the blind, entitled the Guild of Blind Gardeners, was brought before the Oxford Ophthalmological Congress in 1919, and met with warm sympathy. The Guild will be inaugurated on May 26th at the National Library for the Blind, 18, Tufton-street, Westminster, and medical men who are interested should communicate with Mrs. Duncombe, president of the Guild, 1, Stafford Mansions, Buckingham Gate, London, S.W.

Federation of Medical and Allied Societies.—The annual dinner will be held at the Café Royal, Regent-street, London, on Thursday, May 26th. The chief guest will be Dr. Addison, M.P., in recognition of the services which he has rendered, in circumstances of exceptional difficulty, as first Minister of Health. Sir Alfred Mond, M.P., the Minister of Health, will be present, as also will members of the medical group in Parliament, and other guests. Those wishing to attend are requested to make early application to the general secretary, 5 Vere-street, London, W. 1, for tickets, price 12s. 6d., exclusive of any wine taken. Extra tickets are available for private guests, whose names, together with remittances, should accompany all applications.

National Council for Combating Venereal Diseases.—A conference is to be held at the Caxton Hall, Westminster, London, S.W., on Tuesday, May 10th, at 3.30 P.M., for the purpose of hearing reports from the three Commissions which recently returned from the Far East, the West Indies, and the Mediterranean. The meeting will include representatives from Government departments interested in home and colonial health and industrial administration, from mercantile marine associations and shipping firms, and from commercial houses trading with the places visited by the Commissions. Speakers will include Lord Gorell, President of the Council; the Earl of Onslow, Parliamentary Secretary, Ministry of Health; Hon. E. F. L. Wood, M.P., Parliamentary Under Secretary of State for the Colonies; Lieutenant-Colonel L. S. Amery, M.P., Financial Secretary, Admiralty; Mr. D. Bramah, of the Seafarers Joint Council; Dr. Rupert Hallam, Medical Commissioner to the Far East; Dr. Letitia Fairfield, Educational Commissioner to the West Indies; Dr. Winifrid Cullis, Educational Commissioner to the Mediterranean; and Dr. A. F. Wright, M.C., Medical Commissioner to the West Indies. The meeting will be open to the public. Tickets obtainable from the Secretary of the Council at 80, Avenue Chambers, London, W.C. 1.

Chartered Society of Massage and Medical Gymnastics.—The annual meeting of this Society was held on April 16th at Armitage Hall, Great Portland-street (by permission of the National Institute for the Blind). The report of the council was presented by Sir Cooper Perry, the chairman, who said that during its nine months' of existence the Chartered Society had done much work. The Examinations, Training, and Registration, Establishment and General Purposes, Finance, Journal, and Badge Committees had met twice monthly and their various recommendations to council showed that a variety of important matters had received careful deliberation. Requirements for training and for examination had been set out; provisional conditions for entry to registered membership and to additional registers had been publicly announced; an insurance scheme to meet the needs of professional workers was available; lectures and special courses have been given, and arrangements were already in hand for a conference of members to be held in the autumn. The appointments bureau had since July, 1920, supplied 185 members with work. Ten examinations had been carried out by the Chartered Society of Massage and Medical Gymnastics, and 1426 certificates granted. The Chartered Society had appointed representatives to the Massage Advisory Committee (Ministry of Pensions), the British Federation of Medical and Allied Societies, the National Council of Women Workers, and the Federation of Professional Women. The registered membership on March 31st was 2655, consisting of 2464 masseuses and 191 masseurs. The numbers on the additional registers on March 31st were as follows: medical electricity, 677; medical gymnastics, 304; teachers of medical electricity, 38; teachers of medical gymnastics, 39. The effect of Red Cross massage clinics for the treatment of civilian cases on those in private practice was discussed and will be further investigated. It was announced that members of the Chartered Society were to be eligible for membership of the Cowdray Club attached to the College of Nursing.

Harveian Society.—A clinical meeting of this Society will be held at the Paddington Infirmary, Harrow-road, W., on Thursday, May 12th, at 4.30 P.M. Programme will be found in our Medical Diary.

Glasgow University Club, London.—The annual summer dinner will be held on Friday, May 27th, in the Holborn Restaurant, Professor F. O. Bower, F.R.S., in the chair.

Liverpool Samaritan Hospital for Women.—This hospital was founded 25 years ago, and in 1920 there were 7100 attendances and 764 operations. The accommodation has become inadequate, and it is proposed to erect a new hospital building. For this purpose the committee has in hand a sum of £12,163. The proposed new premises are designed to occupy a site bounded on the north by Upper Parliament-street, on the west and south by Lestock-street, and on the east by the Windsor-street Municipal Library. The front will face the end of the cathedral. The out-patient department will open into Lestock-street, and there will be an entrance in Upper Parliament-street for stretcher cases. On the main floor there will be two general and three private wards, an administrative department, and dining- and recreation-rooms for the nurses. On the upper floors will be general wards, private wards, up-to-date theatres, and staff rooms. In the general wards there will be accommodation for 62 patients, and, in addition, there will be eight private wards. The building is to be constructed of rustic brick and Portland stone, and will harmonise in design and style with the eighteenth-century houses in Rodney-street and neighbourhood.

Norfolk and Norwich Hospital.—This hospital has adopted a scheme for attempting to raise funds which presents some novel features. It is calculated that the excess of expenditure over income amounts roughly to £250 a week. A system of payment by patients (both in and out) was started on Jan. 1st this year, and this is found to work most satisfactorily, bringing in an average of £60 a week. The hospital almoner reports that on the whole patients are quite willing to contribute towards the cost of their maintenance and treatment. The workmen's contributory scheme has also been extended, and the most recent suggestion for increasing the revenue of the hospital is that known as the "county parish scheme," according to which each parish in the county is asked to accept the responsibility which properly belongs to it. As a guide to the amount required from each parish, the expenditure of the hospital has been divided amongst the population who might be expected to contribute, and the sum arrived at is 2s. 3d. per head for each parish. This amount could be made up from various sources, such as private subscriptions, workmen's contributions, church collections, &c. This appears a good method of appealing to all persons in the county of Norfolk who are liable at any time to apply for the benefits of hospital treatment and good results are hoped for.

Donations and Bequests.—Alderman James Fildes, of Bowdon, Cheshire, a member of the City Council, Manchester, and for many years chairman of the Public Health Committee, by will bequeathed nearly £13,000 to local charitable institutions, including £2000 to Manchester and Salford Boys' and Girls' Refuges and Homes, £1000 each to Manchester Hospital for Skin Diseases, Royal Infirmary, Manchester and Salford Sick, Poor, and Private Nursing Institution, Manchester City Mission, and three other institutions; and £500 each to the Manchester Surgical Aid Society, Hospital for Consumption and Diseases of the Throat, Henshaw's Blind Asylum, Royal Eye Hospital, and several other local institutions.—St. Mary's Hospitals, Manchester, have received donations from the Hospital Saturday Fund of £905, and from Booth's charities and other sources the sum of £150.—The Manchester Royal Infirmary has received a donation of £1716 from the Manchester and Salford Hospital Saturday and Convalescent Homes Fund, and about £210 from various employees and firms, and from legacies.—By will the late Alderman James Bracebridge Hilditch, of Richmond, Surrey, left £1000 to his wife for any worthy object such as the cure and benefit of the wounded in the war. Among bequests under the same will are £4000 to the Chelsea Hospital for Women towards the building fund, £1000 to the Hospital for Consumption and Diseases of the Chest, Brompton, £2000 to the Royal Hospital, Richmond, £1000 to Dr. Barnardo's Homes, £1000 to the Richmond branch of the Red Cross Society for a benevolent fund for nurses employed at the Star and Garter Hotel, and £100 each to the Richmond Dispensary, London Fever Hospital, Poplar Hospital for Accidents, Royal Hospital for Incurables, Putney, City Dispensary, British Homes for Incurables, and Society for the Prevention of Cruelty to Children.

ANCOATS HOSPITAL, MANCHESTER.—The ninety-second annual report, which has just been issued, states that despite the increase of ordinary income from £8841 in 1914 to £20,237 in 1920 the deficit on the ordinary receipts and expenditure for the past year was £7339, and the institution now owes upwards of £16,000 to its bankers.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Monday, May 9th.

WAR SECTION: at 5.30 P.M.
Annual General Meeting—Election of Officers and Council for 1921–1922.
Paper: Surg.-Commander S. F. Dudley, R.N.: A Few Observations on the Influenza Epidemic as it affected the Royal Navy.

Tuesday, May 10th.

SECTION OF PSYCHIATRY: at 5.30 P.M.
Annual General Meeting—Election of Officers and Council for 1921–1922.

Wednesday, May 11th.

SECTION OF SURGERY: SUBSECTION OF PROCTOLOGY: at 5.30 P.M.
Annual General Meeting—Election of Officers and Council for 1921–1922.
Informal Discussion introduced by the President.

Thursday, May 12th.

SECTION OF NEUROLOGY: at 8.30 P.M.
Annual General Meeting—Election of Officers and Council for 1921–1922.
Paper: Professor Marinesco (Bukarest): Encephalitis Lethargica (communicated by Sir Frederick Mott).

Friday, May 13th.

CLINICAL SECTION: at 5.30 P.M.
Annual General Meeting—Election of Officers and Council for 1921–1922.

SECTION OF OPHTHALMOLOGY: at 8.30 P.M.
Exhibits (at 8 P.M.):
Mr. B. T. Lang: (1) Test Types; (2) Daylight Lamp.
Papers:
Dr. D. Leighton Davies: Lacrymal Obstruction—the Results of the Anastomotic Method of Treatment. (Toti.)
Mr. *Ernest Clarke: Lessons Learnt from 40 Years of Refraction* Work.
Miss J. C. Mann: Specimen of Aphakia in a Human Embryo of 5 or 6 weeks.

HARVEIAN SOCIETY OF LONDON, at the Paddington Infirmary, Harrow-road, W.

THURSDAY, May 12th.—4.30 P.M., Clinical Meeting. The following Cases will be shown:—(1) Cases of Multiple Bone Disease—(*a*) Carcinoma, (*b*) Osteomyelitis, (*c*) Rickety Deformities; (2) Actinomycosis (Thoracic); (3) Osteo-arthritis of Hip (after Albée Operation); (4) Epithelioma of Ear; (5) Tuberculosis of Skin; (6) Gonococcal Septicæmia; (7) Case of Graves's Disease; (8) Cases for Diagnosis. Dr. M. *Berry: Lantern* Demonstration of X Ray Plates. Dr. H. Dutch: Demonstration of Aurorascope.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, May 9th.—Opening of the Summer Session. 12.15 P.M., Dr. Burnford: Pathological Demonstration. 2 P.M., Dr. S. Pinchin: Medical Out-patients. Dr. Morton: X Ray Department. 2.30 P.M., Mr. Baldwin: Visit to Surgical Wards. 5 P.M., Lecture:—Mr. B. Harman: The Education of Children with Defective Vision.

TUESDAY.—10 A.M., Mr. Steadman: Dental Department. 11 A.M., Dr. McDougal: Electrical Department. 12 noon, Mr. T. Gray: Demonstration of Fractures. 2 P.M., Mr. Banks Davis: Diseases of the Throat, Nose, and Ear. 5 P.M., Lecture:—Mr. B. Harman: Blind and Partly Blind Children.

WEDNESDAY.—11 A.M., Mr. MacDonald: Demonstration of Cystoscopy. 12 noon, Mr. Sinclair: Surgical Diseases of the Abdomen. 2 P.M., Mr. Addison: Operations. Mr. D. Armour: Visit to Surgical Wards. 5 P.M., Lecture:—Dr. Owen: The Treatment of Nephritis. (I.)

THURSDAY.—10.30 A.M., Dr. Simson: Gynæcological Demonstration. 12 noon, Dr. S. Pinchin: Diseases of the Heart. 2 P.M., Mr. Baldwin: Orthopædic Department. 2.30 P.M., Dr. A. Saunders: Visit to Medical Wards. 5 P.M., Special Lecture:—Dr. E. S. Reynolds: Some Vascular Lesions of the Brain (open to all medical practitioners).

FRIDAY.—10 A.M., Dr. G. Stewart: Neurological Demonstration. 2 P.M., Dr. Burnford: Medical Out-patients. Dr. Pernet: Skin Department. 2.30 P.M., Dr. Pritchard: Demonstration of Cases (Medical Wards). 5 P.M., Lecture:—Dr. Snowden: Psychical Analysis.

SATURDAY.—10 A.M., Dr. A. Saunders: Medical Diseases of Children. 2 P.M., Dr. Owen: Medical Out-patients. Mr. Sinclair: Surgical Out-patients.

Daily:—10 A.M. Visit of Post-Graduates to Wards. 2 P.M., In-patient, Out-patient Clinics and Operations.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, W.C. 1.

MEDICAL SCHOOL.

MONDAY, May 9th.—2 P.M., Out-patient Clinic: Dr. Hinds Howell. 3.30 P.M., Lecture:—Dr. Saunders: Pituitary Disorders.

TUESDAY, May 10th.—2 P.M., Out-patient Clinic: Dr. Grainger Stewart. 3.30 P.M., Lecture:—Dr. James Taylor: Epilepsy.

THURSDAY, May 12th.—2 P.M., Out-patient Clinic: Dr. Farquhar Buzzard. 3.30 P.M., Lecture:—Dr. Tooth: Disseminated Sclerosis.

FRIDAY, May 13th.—2 P.M., Out-patient Clinic: Dr. Gordon Holmes. 3.30 P.M. Lecture:—Dr. Collier: Aphasia.

Fee for Post-Graduate Course £7 7*s.* C. M. HINDS HOWELL, Dean.

ST. MARYLEBONE GENERAL DISPENSARY, 77, Welbeck-street, *Cavendish-square, W.*

Post-Graduate Course on Infant and Child Welfare.

A Course of Twelve Practical Demonstrations on the Management and Feeding of Infants and Young Children by Dr. E. Pritchard to Qualified Practitioners.

TUESDAY, May 10th.—10.30 A.M., *Demonstration XI., The Training (1) of the Motor Functions of the Digestive System, (2) of the Heat Regulating Functions, &c.*

THURSDAY.—3 P.M., Demonstration XII., The Feeding of Children between 9 Months and 2 Years.

LONDON HOSPITAL MEDICAL COLLEGE (UNIVERSITY OF *LONDON*), Turner-street, Mile End, E.

Courses of Lectures:—

A Course of Fourteen Lectures on Pscho-Neuroses, to be given by Dr. M. Culpin in the Clinical Theatre of the Hospital. Open to Students of the Hospital and to Members of the Profession.

TUESDAY, May 10th.—5.15 P.M., Lecture III.:—The Unconscious.

FRIDAY.—5.15 P.M., Lecture IV.:—Suggestion.

Advanced Lectures in Physiology, to Students of the University and to others interested in the subject.

A Course of Eight Lectures on Reception of Sensory Stimuli, to be given by Prof. H. E. Roaf in the Physiology Theatre.

THURSDAY.—4.30 P.M., *Lecture I.*

ST. BARTHOLOMEW'S HOSPITAL (UNIVERSITY OF LONDON), West Smithfield, E.C.

A Course of Eight Advanced Lectures in Physiology, to be given in the Physiological Laboratory, to Students of the University and others interested in the subject.

TUESDAY, May 10th.—4 30 P.M., Lecture II.:—Prof. M. S. Pembrey: The Secretion of Milk.

TAVISTOCK CLINIC FOR FUNCTIONAL NERVE CASES, 51, Tavistock-square, W.C.

A Course of Ten Lectures on Elementary Psychotherapy, to be given by Dr. H. C. Miller, at the Kingsway Hall, Kingsway, W.C.

FRIDAY, May 13th.—5.15 P.M., Lecture II.: Suggestibility and *Authority; Phantasy and Reality.*

INSTITUTE OF PATHOLOGY AND RESEARCH, St. Mary's Hospital, in the Lecture-room of the Bacteriological Department.

A Course of Lectures on Pathological Research in its Relation to *Medicine, open to all Members of* the *Profession* and Students.

THURSDAY, May 12th.—4.30 P.M., Sir James Mackenzie: The Opportunities of the General Practitioner are Essential for the Investigation of Disease and for the Progress of Medicine.

ROYAL INSTITUTION OF GREAT BRITAIN, Albemarle-street, Piccadilly, W.

TUESDAY, May 10th.—3 P.M., Lecture IV.:—Prof. A. Keith: Darwin's Theory of Man's Origin (in the Light of Present Day Evidence).

THURSDAY.—3 P.M., Lecture:—Dr. C. S. Myers: Pyschological Studies—*(II.) The Appreciation of Music.*

FRIDAY.—9 P.M., Discourse:—Mr. W. Bateman: The Determination of Sex.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE CLINIC.

TUESDAY, May 10th.—4.30 P.M., Lecture:—Prof. G. R. Murray: Treatment of Diseases of the Endocrine Glands.

MANCHESTER FRENCH HOSPITAL POST-GRADUATE LECTURES, 24, Acomb-street, Whitworth Park.

Special Course of Lectures in Gynæcology.

WEDNESDAY, May 11th.—11 A.M., Demonstration Operations.

THURSDAY.—4.30 P.M., Lecture V.:—Dr. A. C. Magian: Malignant Disease of the Uterus.

Appointments.

Successful applicants for vacancies, Secretaries of Public Institutions, and others possessing information suitable for this column, are invited to forward to THE LANCET *Office, directed to the Sub-Editor, not later than 9 o'clock on the Thursday morning of each week, such information for gratuitous publication.*

CORFIELD, C. R., M.D. Brux., L.M.S.S.A. *Lond.*, has been appointed Medical Officer to Swinton and Pendlebury and Stalybridge Ante-natal Clinics.

DARLOW, F., M.B., Ch.B. Vict., Certifying Surgeon under the Factory and Workshop Acts for Horsforth.

HIRSCH, Capt. C. T. W., late R.A.M.C., Honorary Anæsthetist to the West End Hospital for Nervous Diseases.

Vacancies.

Mount Vernon Hospital for Tuberculosis and Diseases of the Lungs and Heart, 7, Fitzroy-square, W.—Asst. S. Also Asst. Res. M.O. £200.
National Hospital for the Paralysed and Epileptic, Queen-square, W.C.—M.O. in charge of Electro-Therapeutic Dept. £100. Also Res. M.O. £200.
Nottingham City Education Committee.—Jun. Asst. Sch. M.O. £537 10s.
Oswestry, Shropshire Orthopædic Hospital.—H.S. £250.
Portsmouth Royal Hospital.—H.S. £150.
Preston and County of Lancaster Royal Infirmary.—H.S £180.
Queen's Hospital for Children, Hackney-road, Bethnal Green, E.—Asst. P.
Queen Mary's Hospital for East End, Stratford, E—Cas. O.
Rotherham Hospital.—Jun. H S. £150.
Royal Free Hospital, Gray's Inn-road, W.C.—Sen. Res. M.O. £200. H.S. £50. Obstet. H.S. £50. Res. Asst. Cas. O. £50.
Royal Naval Medical Service.—Surg.-Lieuts. 26s. 6d. per diem.
Royal Waterloo Hospital for Children and Women, S.E.—Hon. P. and Hon. Gynæcol.
St. Bartholomew's Hospital.—Asst. P.
S. George's Home, Milman's-street, Chelsea, S.W.—Part-time Visit. Asst. M.O. £200.
Sheffield City.—Asst. Tuberc. O. £350.
South Mimms, Barnet, Clare Hall Sanatorium and Hospital.—Asst. M.O. £350.
Taunton and Somerset Hospital.—Sen. and Jun. H.S.'s. £200 and £150.
West Bromwich and District Hospital.—Res. Asst. H.S. £200.
Wigan Education Committee.—Female Asst. Sch. M.O. £500.
Worcester County and City Mental Hospital, Powick.—Sen. Asst. M.O. £450. Also Jun. Asst. M.O. £350.

THE Chief Inspector of Factories, Home Office, S.W., gives notice of vacancies for Certifying Surgeons under the Factory and Workshop Acts at Wath-on-Dearne, Mullingar, and Evesham.

Births, Marriages, and Deaths.

BIRTHS.

O'CONNOR.—On April 29th, at a nursing home, Clifton, the wife of Major A. P. *O'Connor*, M.C., R.A.M.C., of a daughter.

VICKERS.—On April 28th, at Rosslyn, Uxbridge, the wife of Harold Vickers, M.R.C.S., L.R.C.P., of a son.

MARRIAGES.

LANKESTER—YOUNG.—On April 28th, at the Brompton Parish Church, S.W., *Ralph* A. R. Lankester, M.D., to Constance Nevill, eldest daughter of the late Charles Young, of Alton, *Hants*, and Mrs. Young, of Camberley.

MCCLOGHRY—ACHESON.—On April 29th, at Christ Church, Leeson Park, Dublin, Colonel J. McCloghry, F.R.C.S.I., Indian Medical Service (retired), to Hilda Sara Shaw, daughter of [illegible] J.P., Rushill, County Roscommon.

SMITH—GLYNNE.—*On* April 26th, at Princes-road [illegible] Church, Bangor, Dr. Malcolm Smith, of [illegible] Dr. Eryl Glynne, elder daughter of Mr. and [illegible] Jones, of Glyndyl, Bangor.

DEATHS.

HONEY.—On May 1st, at Shutta, East [illegible] Edward Honey, M.D., Staff Surgeon [illegible] 56th year.

[illegible]ICKIN.—On April 28th, suddenly, [illegible] M.R.C.S., L.R.C.P. (late Captain [illegible]

[illegible]ARD.—On April 30th, at [illegible] F.R.C.S., aged 65 years.

N.B.—A fee of 7s. 6d. [illegible] Births, [illegible]

Notes, Short Comments, and Answers to Correspondents.

A CATALOGUE OF EARLY MEDICAL WORKS.

A CATALOGUE of "Early Works on the Sciences of Medicine and Chirurgery," published at intervals by Charles J. Sawyer, Ltd., of 23, New Oxford-street, London, claims, not without good reason, to be the only special list of this class of books issued in Great Britain. But even if this were not so, and if catalogues of this kind abounded, the copy before us would prove of great interest to the medical historian or collector. Among some 400 titles we meet with a tempting *embarras de richesses*, dating in many cases from the epoch immediately following that of early printed books, which ends somewhat arbitrarily in the year 1500. One of the first titles to catch the eye of the curious is the "Practica Nova in Medecina" of Simphorianus Champerius, published in black letter at Leyden in 1517. The work is in its contemporary binding, the boards composed of leaves of MS. covered with a portion of a MS. on vellum. It is a collection of all that has been said concerning every kind of disease by the Greeks, Romans, and Arabs, and the present book is annotated in what appears to be a contemporary hand, which on examination—especially if a signature could be found—might very well prove to be that of Symphorien Champier himself. This famous medical man flourished in the early sixteenth century, was physician to the Duke of Lorraine, and a relative of Bayard the *chevalier sans peur et sans reproche*. He was well known as a historian, and perhaps Bayard may have possessed this volume.

The romance of old books grows on the collector as he examines ownerships as evidenced by old signatures and epigrams in fly-leaves, where surprising discoveries are often made. Another point worth study in old medical works is the illustrated title-page, which is often adorned with curious representations of ancient contemporary practice. The catalogue in front of us reproduces some eight of such scenes. Thus we have a picture from the "Discorsi di Pietro Paolo Magni Piacentino sopra il Modo di Sanguinare" (8vo, bound in limp vellum, Roma, 1586), in which the patient is seen on a curious box-bed in the act of being bled by a barber-surgeon, whose assistant holds tight the end of a ligature, while the physician, in robe and flat cap, looks on in the foreground and ostentatiously avoids touching the figure in front of him. The "De Monstris" of Fortunius Licetus (4to, old calf, Amst., 1665) has a fine title-page, which is probably known to some of us, as it may be found in many medical libraries. The monsters—a woman with five breasts, a child with elephantiasis, and armless men—are shown us on view in a design notable for its artistic composition, vivid lights, and deep shadows.

This Amsterdam edition is far more complete than the earlier ones printed in Padua. Another thick folio of close on 1100 pages has a title-page illustrative of various operations. This is the "Medical Observations of John Schenck," dated at Frankfort in 1609. Such a work may have been known to Shakespeare, as, indeed, others in this collection may have been known to Milton and the great men of the seventeenth century. We can well imagine with what curious interest those old omnivorous men of culture turned over the pages of such a work as Richard Sanders's "Physiognomie and Chiromancie, Metoposcopie, the Symmetrical Proportions, and Signal Moles of the Body," published in London in 1653, or "The Compleat Midwife's Practice, in the Most Weighty and High Concernments of the Birth of Man," 1656. Several of Nicholas Culpeper's works are here offered, and the eighteenth century is well represented, especially with six medical portraits of John Hunter, the charming mezzotint of John Haighton, and a fine old engraved portrait of Garth, after Kneller.

TYPHUS IN SIBERIA, 1919-20.

Captain Francis McCullagh, Royal Irish Rifles, who, captured in Siberia, worked his way through Moscow to England, has written a book of absorbing interest on Russia as she now is, entitled "A Prisoner of the Reds." He cannot tell us how many died of typhus, but he says the mortality (death-rate, probably) was in Siberia in 1918 from 5 to 8 per cent., but in 1920 about 10 per cent. 20,000 cases were reported in the one town of Taiga, two huge piles of unidentified dead bodies were there, one near the station, the other some distance off. 20,000 corpses lay unburied outside another town. In the district between Omsk and Krasnoyarsk practically all the doctors had been attacked, and 50 per cent. had died. One doctor told the author that the highest mortality was amongst middle-aged people engaged in intellectual work, so that the effect on the future education and literary condition of Russia is disastrous, already so shaken by the murders and proscriptions of the Reds. Of 800 staff officers who travelled from Omsk to Krasnoyarsk in a train 26 died. "My whole journey from Omsk to Krasnoyarsk, and from Krasnoyarsk to Moscow was overshadowed by this scourge, as well as by the venereal and other diseases which are fast eating away the vitality of the Russian race, and my fears on the score of typhus were increased by what I saw of the filthy personal habits of the Russians; some of them could not shake the folds of their dress without sprinkling lice on everybody in the immediate vicinity. ...... Going through Russia at the present moment is, owing to typhus alone, as dangerous as going 'over the top' was in France. ...... In the present atmosphere of Russia all human charity withers away. ...... Sometimes when I spoke to a man about his wife or children ...... I heard the phrase 'died of typhus' pronounced in as unconcerned a tone as that in which an Englishman might say, 'Gone to Brighton for the week-end.'" He tells how Trotzky found typhus raging at Ekaterinburg, and causing great losses. He asked the D.M.S. what could be done about it, and listened "with ominous calm" while the D.M.S. placidly told him it would not decrease till April. Trotzky then said with alarming violence, "I am no doctor, but I understand from you that typhus is conveyed by lice. Now, it must be possible to destroy these by some degree of heat that could be produced in some of our public baths, and the soldiers might wash in one part of the bath-house while their clothes are being disinfected in another. I do not believe in fatalism. If I find you do not at once take some steps I will hand you over to the Extraordinary Commission." The Extraordinary Commission is the Commitee of Public Safety, whose prisoners so often fail to reappear. Consequently next day an excellent bathhouse was opened free, and the author had his first bath for three months.

A HANDBOOK FOR THE LIMBLESS.

A USEFUL handbook has just been issued by the "Disabled" Society (48, Grosvenor-square, London, W.1) for the general guidance of ex-Service men of all ranks who have lost one or more limbs. The handbook, which is the work of Captain H. H. C. Baird, D.S.O., is described as a skeleton edition, setting forth the lines along which the next edition will be expanded. The hope is that those who have lost limbs will, in the main, themselves supply the contents of the more comprehensive publication; the provisional edition has been brought out owing to an increasing demand from many quarters for immediate information concerning the supply and use of artificial limbs.

The "Disabled" Society and Its Aims.

The handbook begins by a statement of the advantages obviously to be gained by members of a large society composed of men with similar disabilities; there are approximately 38,000 men who lost a limb or limbs in the recent war, and all are invited to become members and to subscribe to the funds of the Society, which has at present no membership fee. The objects of the Society are briefly as follows:—

1. To assist all who have lost limbs on service, by the collection and registration of all forms of information useful to the wearer of an artificial limb for purposes of trade, business, or recreation.
2. To disseminate this information by means of a handbook posted to the members of the Society, and by publishing from time to time in various journals articles dealing with new types of limbs which may become available.
3. To arrange for lectures, demonstrations, and physical training by experts at centres throughout the country.
4. To organise and maintain a permanent and up-to-date exhibition open to all who have lost a limb, of all the best limbs, appliances, and tools collected from all sources, at home and abroad.
5. To maintain accommodation suitable for the interviewing of members; for the testing of artificial limbs; and for giving instruction in their usage.
6. The aim of the Society is to put its members in the most favourable position for taking their place in the normal life and pleasures of the nation by ensuring that the most suitable limbs are supplied to all.

Medical Advice and Advice from the Disabled.

The Society has made arrangements with St. Thomas's Hospital, London, whereby those with lower-limb amputations can obtain help, advice, and thorough instruction in the use of an artificial limb. Applications for the facilities thus offered should be addressed to the Secretary of the Society, at the address given. Reference is also made in the handbook to the well-known Surgical Supply Depôt, Kensington, which is continuing the work done during the war for the benefit of ex-Service and other civilian patients. The "Disabled" Society's preliminary researches have already resulted in the collection of much valuable information; a short selection of interesting details supplied by one-legged and one-armed men shows how ingenious the crippled man may be, and how ready he is to help those with disadvantages similar to his own. Although much of the information given cannot, of course, be applied to cases of double amputation, one remarkable instance of perseverance by an armless man is quoted and will doubtless encourage others; this man not only learnt to write with his teeth, but when he received artificial arms taught himself to use a fork, cycle, dig, and play billiards and the piano.

Pensions : The Committee and Local Pensions.

The functions of the Local War Pensions Committees are described, and an extract is given from the First Schedule of the Royal Pensions Warrant of December, 1919, containing detailed regulations regarding pensions, allowances, treatment, constant attendance, initial supplies on discharge from the Service, renewals and repairs, and chairs and tricycles. A note on the fibre-cone "peg-legs" supplied by the British Red Cross completes this useful section.

A brief description is given of the industrial training made available by the Ministry of Labour, together with notes on the Maintenance and Training Grant Scheme, the Business Training Scheme, and the Disabled Soldiers' Sections of Employment Exchanges. The Civil Liabilities Scheme is also explained, and the work of the ex-Service men's adviser. The handbook closes with a few general notes for officers, and with an appeal to all who have lost a limb to support the Society and make it widely known. The price of the handbook is 6d., and all proceeds from its sale go to the funds of the Society.

THE BUFF BOOK.

To the Editor of THE LANCET.

SIR,—In reference to your paragraph on this question in the issue of April 30th, I think you will be interested in the following sequence of events:-

1. I informed the publishing company of the decision of the Council of the R.C.V.S. that members would be required to refrain from inserting paid announcements in the Buff Book.
2. The secretary of the publishing company replied, stating that they had decided to include in the Buff Book the names of all professional gentlemen free of charge.
3. I pointed out that the form given in the book referred to "traders," and made no special mention of professional men. I asked whether it was not true that unqualified practitioners, who would be liable to prosecution if they used a professional title, also had the right to the free insertion of their names in the Buff Book, and the further right, denied to qualified members of the professions, to pay for an insertion in the boldest type obtainable. This would be manifestly unfair to the members of the professions, and misleading to the uninstructed public.
4. The managing director replied stating that the secretary was somewhat premature in stating definitely that they had decided to include the names of professional gentlemen free of charge. It was in contemplation, but no decision had been taken. With regard to my question as to the rights of unqualified persons, he agreed that my supposition was correct, and added: "You will readily understand that it is impossible for us to enter into the ethics of professional objections, and having regard to the heavy expenses to which we are put in delivering a free copy to every telephone subscriber we cannot refuse business." He then made the following suggestion: "There is a simple way out of the difficulty and, I think, one that would be of distinct advantage to practising veterinary surgeons—namely, for your Institute to reserve a page or two in the book for qualified surgeons and pay for the same out of the College funds. As there would not be any cost to the company for canvassing, we should be prepared to quote you special terms. Perhaps you will consider this suggestion and let me hear from you? It would, of course, be understood that no advertisement whatever appeared on the pages so reserved."

I have not answered this letter. But one is entitled to wonder whether the manager, who cannot enter into the ethics of professional objections, has visions of the Law Society, the General Medical Council, and the other governing bodies of the professions subsidising the Buff Book and acting as agents in place of canvassers so as to provide the complete lists of professional men with their telephone numbers, while at the same time reserving to himself the right to accept advertisements from any quack who rents a telephone, and to give him a whole page, if he pays for it, in proximity to the lists of qualified men.

I am, Sir, yours faithfully,
FRED. BULLOCK,
Secretary and Registrar, Royal College of Veterinary Surgeons.
10, Red Lion-square, W.C., May 3rd.

CONVALESCENT HOME FOR MIDDLE-CLASS WIVES AND BABIES.

A COTTAGE at Farnham, formerly the home of Sir James Barrie, has been adapted as a convalescent home for six recently confined mothers and their babies. The intention is to help the wives of professional and business men who find it difficult to get suitable and reasonable accommodation. The cottage is well furnished, fitted with radiators as well as open grates, and the presence of an experienced matron, a nursery nurse, and an adequate domestic staff, will ensure to the mother a real holiday before she returns to her home duties. The inclusive terms are 35*s.* a week for the smaller and £2 2*s.* for larger rooms. Special arrangements as to fees can sometimes be made. If desired, a bedroom can be procured for the husbands at Farnham, who can have meals at the cottage at a small payment. Mothers are received on a doctor's recommendation only, and can stay for a period of one to four weeks.

Full particulars can be obtained from the Matron, Black Lake Home, near Farnham, Surrey, but all applications must be made to owner of the cottage, the Hon. Mrs. Gerald S. Montagu, Great Fosters, Egham, Surrey.

THE LIGHTING OF SHIPS.

IN a paper on "Ship-lighting in Relation to Comfort, Safety, and Efficiency," read before the Illuminating Engineering Society on April 26th by Mr. W. J. Jones, the hygienic advantage conferred on ships by the introduction of electric lighting is noted. It diminishes the vitiation of the limited air-supply. The first ship to be recorded as fitted with electric light was built in 1879, and it was about 1883 that electric lighting was introduced into the navy in H.M.S. *Polyphemus*. Mr. Jones emphasises the great advantage of painting the inner surfaces of ships white, as this enables sufficient illumination to be given with fewer lights, and diminishes the glare from naked lamps. The White Star Company having permitted him to examine the illumination of *Olympic*, he found this "distinctly pleasing and comfortable." He quotes the illumination three feet above the deck as follows:—In white painted alleyways (passages) 0·5 candle-power per square foot, in the first-class cabins 1·0, in the first saloon 2·5 candle-power. It will be remembered that the *Olympic* was reported[1] by our own representative to be unusually well ventilated. We are glad to find it urged that white-painting of the inner surfaces of ships results in economy, as it may thus become more usual. It certainly makes a ship more healthy to be white painted within, for she can be, and must be, better cleaned, the white paint "showing up the dirt."

CARAVAN SQUATTERS.

A QUESTION was recently asked in the House of Commons concerning the petition of the Moreton (Cheshire) District Council upon the subject of the caravan settlement in that and adjoining parishes. The settlement is said to contain about 1100 caravans, many of which are only nominally vehicles, being supplied with bogus wheels. During the summer months numerous tents are added, and the population of the settlement is increased to many thousands. The drainage system, latrines, and urinals are described as wholly inadequate and insanitary, and admit of little hope of improvement; the land is below high-water mark, and becomes a quagmire in wet weather. Excreta, washing refuse, and food scraps thus collected attract swarms of flies, and there is grave danger of an epidemic amongst the caravan population and that of the surrounding district, to which the state of affairs has become an intolerable nuisance. Sir Alfred Mond replied to the effect that the local authority had sufficient powers to deal with the serious factors of the situation, and that he was in touch with them concerning the matter.

It is not clear what proportion of this settlement consists of gipsies or to what degree the conditions of the camp are due to their presence. A recent protest by the people of Whitton, in Middlesex, against a small invasion of gipsies was countered by the vicar of the village, who expressed his satisfaction at their large attendance at church and at the reverent behaviour of the crowd which collected at an open-air service held among the caravans. It would seem possible, however, that the caravan town in Cheshire is largely tenanted by victims of the housing shortage, taught by army life to make the best of an unpleasant situation—unless, indeed, experience of strange lands has stirred to life an atavistic wanderlust in the descendants of generations of townsfolk and agriculturists. The best way to avoid creation of such potential centres of disease is to build houses; the man who, in the words of the war artist, "knows of a better 'ole" will generally "go to it."

---

[1] THE LANCET, 1920, ii., 666.

CENTRAL COUNCIL FOR DISTRICT NURSING IN LONDON.

A DIRECTORY of district nursing and streets list for London, which first appeared in 1917, is now issued at 2*s.* 6*d.*, with a 1921 supplement. It contains, besides a comprehensive list of streets, with an index number indicating the district nursing association from which it is served, the addresses of divisional offices of the Public Health Department of the London County Council and of children's care offices; also particulars of the ambulance service of the Metropolitan Asylums Board. Lists are given of boards of guardians, of boroughs and corresponding Poor-law areas, of city and borough councils, of hospitals (general and special), with addresses and telephone numbers, and of maternity and child-welfare centres. Particulars of nurses attached to religious organisations, associations of midwives, facilities for massage and for material relief in sickness are also added. We note as trivial errors the omission of any hospitals for diseases of the chest among the special hospitals mentioned (pp. 6 and 7), and the fact that the Chartered Society of Massage and Medical Gymnastics is still alluded to under its old name (p. 8).

HOW NOT TO PREPARE A MEDICAL ARTICLE.

WE referred last week to a useful pamphlet drawn up by the Publications Department of the Medical Research Council containing a series of Notes upon the Preparation of Monographs and Reports for Publication by the Council. With the advice therein given we cordially concur except that we should much prefer the abbreviation of the gramme and its derivatives to follow the procedure laid down by the Council of the Chemical Society, i.e. :—

kilogramme, kg. or 1000 g.;
gramme, g.;
centigramme, cg. or 0·01 g.;
milligramme, mg. or 0·001 g.;

and not kgm., gm., cgm., mgm. as given in the Notes. And we should have welcomed some warning against the tendency to spurious accuracy in giving decimal fractions of more significant figures than are justified by the number of cases dealt with.

The March issue, we are now reminded, of the *American Journal of Surgery* contains an opportune leading article on how *not* to prepare a medical article which inculcates the same lessons in the Belloc method of a cautionary tale. A few extracts from this entertaining publication may induce our readers to turn to the original, which opens with the advice :—

> If you feel the urge—or the need—to write a medical article, *don't—don't restrain yourself* merely because you have nothing new to say and hardly know how to say it! Facts and theories in medicine must be repeated again and again to drive them home. Remember that not all your colleagues read the same text-books that you do, and therefore it is your duty to disseminate their information. If, at the eleventh hour, you have hastily scratched off a "pot-boiler" as your contribution to a "symposium," don't waste it on the limited audience of a medical society—publish it!

Another paragraph treats of the choice of language for a medical article in a manner reminiscent of Lewis Carroll's reminder to the would-be poet: Then, fourthly, there are epithets that suit with any word, as well as Harvey's Reading Sauce with fish, or flesh, or bird :—

> There are certain words and expressions that belong in every medical article. Be sure to use them. These are: "Cito, tuto et jucunde," "fons et origo," "pari passu," "marked," "throws light," "presented," "examination revealed," "symptom-complex," "interesting and instructive," "significant observation," "points out," "unexplored fields." (There is room in almost every article to scatter a few small "fields.") When reporting a case refer frequently to "patient," but never write "the patient died"; say "ceased" or "exitus lethalis."

The advice given to the author on the difficult subject of references is full of subtle malice, and we could wish that it had no applicability to cis-Atlantic writers :—

> Embellish your article with references. If you wish, you may add to it a bibliography taken from a recent paper on the same subject. If that is not convenient you may, on the other hand, simply append the names of a few text-books without indicating what parts of them are concerned. Either way is acceptable, under the rules. If you quote or refer to a few publications, gather these titles at the end of the manuscript and label them sententiously "bibliography," not merely "references." Don't bother to read these publications in the original, nor to verify the accuracy of the references themselves, or of their dates, or of the authors' names. Especially avoid any uniformity in arranging these titles. Abbreviate the names of journals in as many different ways as you can. Give only the volume number, not the date; the reader can discover in a library what year the article was published. References to articles in weekly journals, however, should be simply by the year and the page number; anyone that wants to can find out for himself whether it was in the first or second volume of that year. Don't spend ten cents to buy the little pamphlet on *The Bibliographic Style of the Journal of the A.M.A.*; you might be tempted to follow its scheme of abbreviations of journal titles. Establish your own style, or, better yet, avoid all style.

Finally, the need of a revised medical dictionary is indicated in which Temperature shall be synonymous with Fever, Pathology used to indicate the Disease removed from an organ at operation, and Wassermann, Babinski, and Romberg stand for reactions (or "pathologies"), and not for once distinguished physicians and investigators.

A MEMORIAL TO THE LATE DR. ERNEST ROBERTS.

AN appeal is being issued by the Minories (Stepney) Centre of the Women's League of Service for Motherhood for an endowment fund of £6000 as a memorial to the late Dr. Ernest Roberts, the founder of the Centre, who died last year. The scope of the work includes infant consultations, clinics, medical advice and dental aid for mothers; dinners for expectant and nursing mothers; a creche; supply of clothing for children (at cost of materials); needlework, nursing, and other classes. Concerts and entertainments for the mothers are arranged, and home visiting is done by a trained nurse. Medical clinics and country convalescent holidays for specially delicate children have hitherto been financed by Dr. Roberts himself, save for the mothers' small contributions. His brothers have undertaken to help the drug department; for the Children's Country Convalescence Fund extra help is required. Contributions should be sent to the honorary treasurer, Mrs. W. B. Gladstone, 32, Prince's Gardens, London, S.W. 7.

COLONIAL HEALTH REPORTS.

Jamaica.—In the report for 1919-20 the population is estimated at 893,580. The birth-rate worked out at 33·5 and the death-rate at 22·2 per 1000. Of the total deaths 32·6 were those of children under 2 years of age, and of these 24·4 were those of children under 1 year. The principal causes of death among the inhabitants of Kingston, the capital, were: Phthisis, 11·3; diarrhœa and enteritis, 10·4; heart disease, 7·0; atrophy, icterus, and scleroma of the new-born, 6·9; pneumonia, 4·0; influenza, 3·2. Matters in connexion with health and sanitation have been receiving for some time past the earnest attention of the Government, and active steps were taken during the year. The Rockefeller Foundation began extensive operations in connexion with the treatment of hookworm, and the United Fruit Company inaugurated a system for medical attendance on their employees. A great diversity of climate is obtainable in the island. From a tropical temperature of 80° to 86° F. at the sea coast the thermometer falls to 45° and 50° on the tops of the highest mountains, and with a dryness of atmosphere particularly delightful and suitable to the most delicate constitution. There are many mineral springs, some of them possessing valuable qualities for the cure of various diseases and infirmities of the body; the two principal are the spring at Bath, in St. Thomas-in-the-East, and the spring at Milk River, in Clarendon.

British Guiana.—In the year 1919, when the population was estimated at 305,991, the birth-rate was 26·0 and the death-rate 40·4 per 1000. The deaths of children under 1 year of age were 185 per 1000 births. The following table shows the variation of the birth- and death-rates amongst the different races :—

—	Birth-rate.	Death-rate.
Portuguese	23·0	35·5
Europeans other than Portuguese ...	10·9	10·1
East Indians	24·6	49·3
Chinese	28·0	31·2
Blacks	26·8	33·2
Mixed races	27·2	22·4

Enteric fever is a notifiable disease, and during the year 524 cases were notified with 112 deaths. Anti-malaria and anti-mosquito measures are being generally and gradually enforced, with visible signs of success. In 1906-7 33,748 cases of malarial fever were treated in the sugar estates' hospitals; in 1919 the numbers fell to 7046. Quinine has been for some years sold at all post offices to the general public at cost price. It is also distributed by the sugar estates free to their labourers. Ankylostomiasis, which has engaged the attention of the Medical Department for several years, has considerably decreased on the sugar estates; this is attributed to improved sanitary measures and the erection of latrines. There were 683 patients in the public hospitals at the beginning of 1919, and during the year 15,007 were admitted. There were 1634 deaths. Out-door treatment was given to 48,697 persons. At the leper asylum there were at the beginning of 1919 194 males and 76 females—total 270—and during the year 72 more were admitted. The total rainfall for the calendar year at the Botanic Gardens, Georgetown, was 84·16 inches, and the total amount of bright sunshine recorded during the year was 2602·7 hours.

LIBRARY

The Goulstonian Lectures

ON

GLYCÆMIA AND GLYCOSURIA.

Delivered before the Royal College of Physicians of London

BY GEORGE GRAHAM, M.A., M.D. CANTAB.,
F.R.C.P. LOND.,
SECOND ASSISTANT, MEDICAL CLINIC, ST. BARTHOLOMEW'S HOSPITAL;
ASSISTANT PHYSICIAN, GREAT NORTHERN CENTRAL HOSPITAL.

LECTURE II.[*]

(Delivered on March 3rd, 1921.)

IN my first lecture I spoke of the fate of the sugar which is in the blood after a meal, and in this lecture I shall speak of some of the conditions under which sugar is excreted in the urine.

CONDITIONS UNDER WHICH SUGAR IN EXCRETED IN THE URINE.

It is incorrect to say that every patient who passes a reducing substance in the urine is suffering from diabetes mellitus. Before that conclusion is possible the nature and amount of the reducing substance must be investigated, and even if dextrose is present the diagnosis is not necessarily correct. Fehling's solution is still usually employed in testing for sugar, and if the test is going to be of use its faults and fallacies must be learnt. First, the solutions A and B must be freshly mixed, for an old solution may reduce itself. Secondly, equal quantities of urine and mixed solution should be boiled separately, mixed when boiling, and not re-heated. If sugar is present in a concentration of over 0·5 per cent. a reduction takes place almost instantaneously; if a concentration of 0·1 or 0·2 per cent. be present the reduction may not take place for five or even ten minutes.

When a delayed reduction of this kind occurs it is always necessary to confirm the presence of sugar by other tests—e.g., Benedict's or Nylander's. In order to be quite certain of the presence of a sugar it is necessary (1) to do a fermentation test with yeast to see if the sugar will ferment; (2) to determine whether the plane of polarised light is rotated to the right or left; (3) to prepare the glucoasazone and to determine the melting-point of the crystals.

Fehling's solution, unfortunately, is reduced by other substances—e.g., uric acid, creatinine, and salicyluric acid, and it would lead to less confusion if Benedict's solution were substituted, as the latter is not affected by these other substances. Benedict's solution is used rather differently, as 5 c.cm. of the reagent and eight drops of urine are boiled together for about two minutes, and then allowed to cool. If only a trace of sugar is present precipitation takes place slowly and is green in colour. The limit of detection is about 0·08 per cent.

Sugars other than Dextrose Found in the Urine.

The other sugars which are found in the urine besides dextrose are lævulose, lactose, and a pentose.

Lævulose may occur in urine either alone or with dextrose. It is a somewhat rare occurrence for lævulose to be present by itself, and as I mentioned in my first lecture, it is regarded as a sign of liver inadequacy. As lævulose gives the same reduction test as dextrose it can only be differentiated (1) by determining whether the solution is lævorotatory, (2) by using Seliwanow's test. The presence of lævulose in the urine does not necessitate a diagnosis of diabetes. It should, however, direct an inquiry into the state of the liver as far as that is possible. Mild restrictions of the carbohydrates are usually sufficient to prevent the excretion of lævulose.

Lactose is only present in the urine of women who are lactating or who have had to cease suckling a child, and in infants with gastro-enteritis.[1] The reduction with Fehling's solution is not quite the same as with dextrose, as it often does not reduce copper unless the mixture is re-heated, but in the last case I saw that the urine reduced Fehling's solution just as dextrose does. This sugar is dextrorotatory, and the osazone is difficult to prepare; it does not ferment with yeast. Once the diagnosis is established the patient needs no treatment, as the condition is one which will right itself in time. An ingenious method of distinguishing between these sugars by means of the ferment action of various higher fungi has been devised by Castellani.[23]

Pentosuria is a rare freak, and until recently no case had been recorded in England, although Sir Archibald Garrod sought for it diligently. Cammidge,[1] however, has recently reported no less than 7 cases; of these patients, 3 were Jews and 2 were Greeks. The sugar reduced Fehling's and Benedict's solutions, but only slowly, as the amount of the sugar was small. Bial's test in the best test for a pentose, and the presence of glycuronic acid, which also gives this test, can be excluded, as it does not give a positive test with Benedict's solutions. Pentose is not fermented by yeast and is usually optically inactive, but may be dextrorotatory. Removal of all carbohydrates from the diet caused no reduction in the pentose, but a diminution in the protein caused a decrease in the pentose output.

So-called Diabetes Innocens.

Dextrose is excreted in the urine in a number of other conditions besides diabetes—e.g., in exophthalmic goitre and acromegaly, and after adrenalin injections—but it would take me too far afield to describe all these types. I will therefore confine myself to the cases of true diabetes and to those groups of rare cases in which sugar is excreted without causing any symptoms, dealing with this latter group first. It has only been recognised comparatively recently that there are patients who pass sugar year in and year out without suffering any ill-effects.

Klemperer,[3] in 1896, described the case of a man who was suffering from renal disease, but also passed a little sugar. Lütbje[3] and Bönninger[4] reported similar cases, and Lüthje observed that the amount of sugar excreted bore no relation at all to the amount of sugar eaten and that the amount of sugar in the blood was less than normal. As these cases all had albuminuria the name "renal diabetes" was suggested. Since then numerous cases of a similar type, but with no signs of renal disease, have been described and that name has been abandoned. Salomon[5] has suggested the title of "diabetes innocens" as the disease seemed such an innocent one. This name is a bad one as the word diabetes indicates that much urine is excreted and in these cases there is no increase in the output of urine. However, the name is now well recognised and cannot well be altered. During the last few years a good many more of these cases have been described, and the total number is approaching 30.[6] [7] [8] [9] [10] Pavy undoubtedly recognised this type, as in 1908 he told a man, whom I saw afterwards, that he had "a family idiosyncrasy involving a slight defect of the carbohydrate assimilative power," and added that he had seen similar cases.

The characters of the class are as follows:—

The sugar is usually discovered by accident and is small in amount, less than 5 g., often only 1 or 2 g., in the day. The amount of sugar excreted does not depend on the amount of carbohydrate eaten, and a dose of 100 g. produces no increase in the amount of sugar. The amount of sugar in the blood lies within normal limits, and in my cases it responded to a dose of carbohydrate in the usual way. Salomon stated that the level of the blood sugar was unaltered by a dose of sugar after one hour, but he worked before it was recognised that the rise in the blood sugar was a rapid one, followed by a rapid fall. The after-history of these cases shows that whether they are treated or not, they continue to pass sugar in small amounts, and that in the end no restrictions are placed on them. As to causation practically nothing is known. The condition is apt to occur in several members of a family. Salomon described 10 cases; 5 of them belonged to two families, and two first cousins of one of the families were affected; while a sixth patient had a sister who passed sugar. I have only seen three of these cases, but one of the patients had a sister and brother who passed sugar. Consanguinity does not seem to play any part in the causation.

Sugar in the Urine with no Symptoms of Diabetes.

There is another group of cases[13] which differs from this group in some points.

The group might almost be called the St. Bartholomew's group, as two of the cases were patients of Sir Archibald Garrod, the third was one of the residents of the hospital, two others were officers (one naval and one military) who came to the hospital to have their blood sugar tested, and the sixth case was reported by Dr. Parkes Weber,[11] an old

---

[*] Lecture I. appeared in THE LANCET of May 7th, p. 951.

No. 5098.

St. Bartholomew's man. Besides these 6 cases I only know of 3 others, those reported by Bailey,[12] and Lewis and Mosenthal,[13] and perhaps by Murlin and Niles,[14] which seem to resemble them. Most of the cases were discovered accidentally. The first one came to Great Ormond-street, complaining of nocturnal enuresis, and the sugar was discovered in the course of a routine examination. Two years later the urines of the father, mother, and brother were examined and that of the brother contained sugar. Two cases were discovered during examination for life insurance. On man was ailing and the sugar was found in the course of the routine examination. None of the patients complain of thirst and they have no symptoms which suggest diabetes.

The chief characters of the group are:—

The amount of sugar excreted is fairly large, 10-30 g. a day, which is much larger than in the case of the previous group. The amount of sugar excreted seems to be almost independent of the amount of sugar eaten. In one of Garrod's cases the sugar output and sugar intake is shown in the following table:—

Sugar intake (grammes).	*Sugar output* (grammes).
64	39-42
56	20-33
28	23-30
0	20

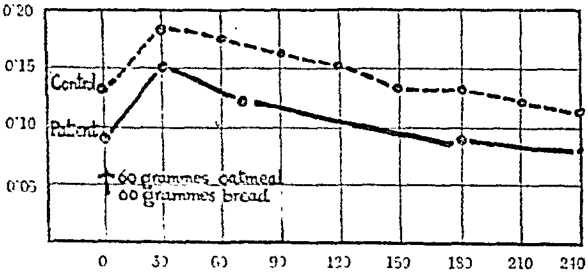
The concentration of sugar in the urine is high—often over 4 per cent. if the urine is collected immediately after a meal. This, again, contrasts with the other group, in which it is usually less than 0·5 per cent. Starvation for a whole day reduces the sugar to a mere trace or to nothing at all. Starvation did not affect the patients adversely, and one of them used to play tennis both morning and afternoon of the hunger day. The sugar returns again as soon as food is given, even if the food contains no carbohydrate. The level of the blood sugar taken when the patient is fasting lies within normal limits, yet sugar is often excreted during a fast.

Sugar Tolerance.

This must be tested by giving a dose of sugar or a carbohydrate meal and determining the effect of the meal on the level of the blood sugar. The urine is collected before the experiment begins and for each hour afterwards. The curves, one from a published case (Fig. 1), the other from a recent case (Fig. 2), show that (1) sugar is excreted when the level of the sugar is normal, though in one case no sugar was excreted on one occasion; (2) the response to the dose of sugar is no greater than that of a normal individual to a similar dose; (3) more sugar is excreted when the level of the blood sugar is raised; in one case sugar continued to be excreted in considerable amounts, although the blood sugar had fallen almost to the original level.

The criticism has been made that these may be mild cases of diabetes, but a mild case of diabetes differs from this type of case in response to the above tests. A mild diabetic who is passing 20-30 g. of sugar in the day will respond to the tests in the following way: (1) the sugar will not be present in each specimen—the urine after the meal will contain most sugar and the fasting urine will not contain any; (2) the amount of sugar will bear some relation to the amount of carbohydrate in the diet; (3) a starvation day will cause all the sugar to disappear; (4) on gradually increasing the diet no sugar will appear for an indefinite period depending on the severity of the disease; (5) if the sugar tolerance is tested with a dose of sugar and the blood curve determined at the same time, the picture is very different. (Fig. 3.) The figure shows that no sugar is passed when the blood sugar is normal, but that the sugar in the blood increases rapidly after the meal and goes up much higher than in the normal person, and that sugar is excreted when the blood sugar is high.

In all the charts the figures at the left side indicate grammes of sugar in 100 g. blood.



The figures at the foot of Charts 1 and 2 represent minutes after meal.

FIG. 1.—Showing the effects of 60 g. oatmeal and 60 g. bread on level of blood sugar.

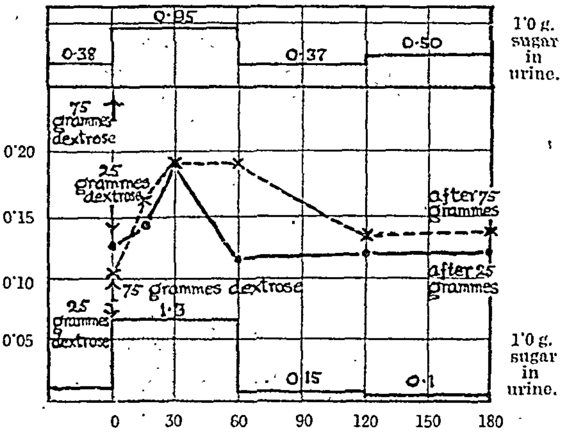


FIG. 2.—The effects of 25 and 75 g. sugar on level of blood sugar (shown by curves); and on sugar excretion in the urine (shown by stippled graphs).

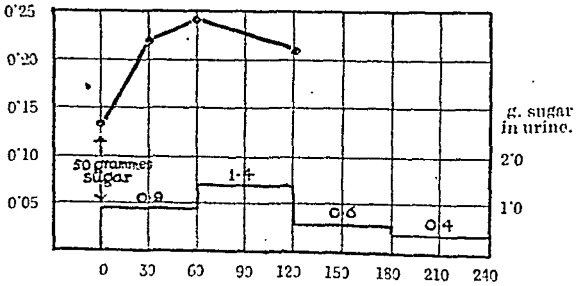
No Treatment Required for Diabetes Innocens.

It is very important to make this distinction clear, as it is a mistake of the first magnitude to make a diagnosis of diabetes innocens unless the case has been tested in the way I have described.

A case of diabetes innocens needs no treatment, but if the patient is treated as a diabetic no harm will ensue; sooner or later he will abandon the treatment with no ill-effect.



The figures at the foot of Charts 3, 4, and 5, represent minutes after sugar.

FIG. 3.—Showing effect of 50 g. sugar on level of blood sugar and on sugar excretion in the urine.

The sister of one of the patients in group 1 endured a fairly strict treatment for two years, but then abandoned it. Later on she married and bore a child with no ill-effects. The child does not pass sugar, but the mother still does so. But if a mild diabetic is treated as a case of diabetes innocens he will inevitably grow worse. I have known this happen on one occasion in the early days of blood sugar determination before the cases had been properly worked out. The man was a diabetic of about two years' standing, and he had become sugar free with carbohydrate restrictions. At this stage his case excited interest, and his blood sugar was determined and found to be normal. The patient was therefore thought to belong to the innocens class, and no diet restrictions were imposed. Two years later he was shown to me as a case of diabetes innocens which had been converted into a case of true diabetes mellitus. His old notes were available, and we were able to obtain the story which I have told you. Unfortunately the man did not respond to treatment as well as he had done before, and three years later he died. The diagnosis of diabetes innocens must therefore be made with great care.

Prognosis as yet Uncertain.

The prognosis in these cases is a little uncertain, as they have not been known long.

Dr. Parkes Weber's case has been watched longest but not continuously. She was in St. Mary's Hospital 35 years ago, and then passed 30 g. of sugar a day. She was in the German Hospital five years ago for a multiple polyneuritis of uncertain causation which got quite well. She was still passing about 30 g. of sugar in the day on a mixed diet. Sir Archibald Garrod's first case has been watched for nine years; the girl, first seen at the age of 8, is now 17, and the boy, first seen at the age of 12, is now 19. Both of them seem very well and lead active lives with no restrictions. One of the men, first seen nine years ago, is still quite well. The other two cases are only of short duration, less than two years. Bailey's case has been watched for eight years. It is clear that these cases are of an innocent type, but various questions arise in connexion with them. Should they marry? Should they live in a hot climate? What should be the attitude of the life insurance offices to them? So far two of my male patients have married, and one of them only came to me to know if he might marry. It was with considerable diffidence that I answered Yes, and I failed to satisfy the prospective father-in-law completely. Hot climates do not seem to agree with cases of the milder type of diabetes innocens. One of Garrod's patients was unwell in India. One of mine in group 1 became very slack in Egypt and lost a great deal of weight. In spite of this evidence, however, one of the recent patients persisted in going to Assam, though another one was deterred.

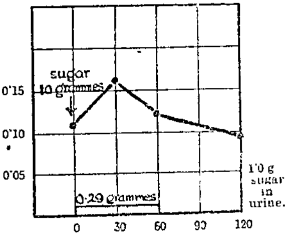


FIG. 4.—Showing effect of 10 g. sugar on level of blood sugar and on sugar excreted in the urine.

The correct attitude of the insurance company is still more difficult. The disease as an entity is a new one; the cases have only been fully worked out since 1916. It is perhaps too much to expect that the innocency of the disease will be admitted, but I believe that the time will come when a case which has been properly worked out will be accepted at low rates by the insurance offices.

The treatment of these cases does not seem to matter. One of my army officers was treated on modern lines for three months without any effect. The only possible line of treatment lies in the discovery of how to alter the leak-point, and of that we at present know nothing.

Exceptionally Large Sugar Excretion.

In the two groups I have described the sugar output was less than 10 and about 30 g. per day respectively. Galambos[15] has described a case where 100–150 g. of sugar per day were excreted. These amounts are very large and in the ordinary way the patient would undoubtedly be considered to be a true diabetic. The case was carefully worked out and it seems certain that sugar was passed, although the blood sugar was not raised. As the amounts of sugar which were excreted are so large I have thought it better to place this case in a separate group, of which it is the only member, although it only differs in degree from the other groups.

Position of Leak-points.

All the cases I have seen in the two groups of diabetes innocens have leaked sugar with a normal blood sugar of 0'09 to 0'11 It is difficult to believe that there is a hard-and-fast division between the diabetes innocens class and the healthy people. So far I have only come across one patient in whom the question has arisen.

He is a boy, aged 6, who has been passing sugar irregularly for the last two years. He has been fairly strictly dieted by Dr. Ernest Young, and seems quite well. He can eat 15 g. of sugar in the form of bread, &c., at each meal of the day without passing sugar. (Fig. 4.) A dose of 10 g. of sugar sent up the blood sugar from 0·11 to 0·16 in 30 minutes, but it was down at 0·12 in 60 minutes and to 0·09 at the end of two hours. During the hour he passed 0·2 g. of sugar, and none in the next hour. His leak-point is set somewhere between 0·12 and 0·16. I am still in doubt as to the correct diagnosis, but I am in no doubt at all as to the correct treatment. With our present knowledge he must continue to be treated as a true diabetic with restricted carbohydrates. To treat him as a member of a new innocens type would be far too great a risk.

In the class of diabetes innocens the leak-point is set at the 0'10 or 0'12 level, and consequently sugar escapes all the time, but most of all after a meal. In the cases that I am now going to describe, the leak-point is not set at 0'20, but may be at 0'25 or 0'27, or higher.

The first case to which I want to refer is one which Garrod[16] first reported in 1912. The patient, a man of 58, came to St. Bartholomew's Hospital in 1909 complaining of thirst and jaundice of three days' duration. The liver was enlarged, reaching four fingers'-breadth below the costal margin; the total output of sugar was not large, 42 g. a day. Under the dietetic treatment then in vogue the sugar was reduced to 4 g. a day in the course of five weeks; the jaundice disappeared in two weeks. After discharge from the hospital the sugar disappeared from the urine and did not return, although the patient ate a liberal diet and no sugar was passed after 100 g. Garrod reported the case in 1912 as one of diabetes with complete recovery of tolerance. In 1915 I[17] made an estimation of the blood sugar at Sir Archibald Garrod's request. He was not passing any sugar at this time, but his blood sugar was 0·26 g. per cent. and a week later it was 0·27 per cent.[10] In 1919 I made sugar tolerance tests with 25 and 50 g. of sugar. (Fig. 5.) The dose of 25 g. did not raise the blood sugar above 0·185 and no sugar was excreted. The dose of 50 g. raised the level of the blood sugar to 0·30 at the end of one and a half hours and 1 g. of sugar was excreted in the urine in two hours. A consideration of the curves shows that the patient now has a distinctly lowered sugar tolerance, but that he does not pass sugar as a rule because the leak-point is set at an unusually high level.

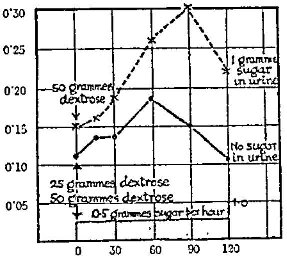

FIG. 5.—Showing effect of 25 g. and 50 g. sugar on level of blood sugar, and effect of 50 g. sugar on sugar excretion in the urine.

The leak-point may also be raised in cases of severe diabetes. I[17] estimated the blood sugar of one man six times on each of two successive days. (Fig. 6.) On the first day 40 g. of sugar in the form of carbohydrate were eaten, and 45 g. of sugar were excreted in the day period of 12 hours and 55 g. in the night period. The blood sugar varied between 0·36 and 0·29 during the day. On the second day tea and coffee with no milk and sugar were given, and only 2 g. of sugar were excreted in the day urine and none at night. The level of the blood sugar varied between 0·27 and 0·29 throughout the day. This man went out of hospital sugar free, and remained well for two and a half years during the war period in spite of its great difficulties about food. He then developed phthisis and died of tuberculosis six months later, three and a half years after the first symptoms of disease.

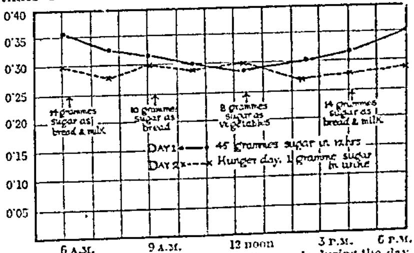

FIG. 6.—Showing level of blood sugar after meals during the day, and on a hunger day.

The blood sugar may be considerably raised in pneumonia and nephritis without sugar being excreted, figures up to 0·28 being reported.

Two Cases in Children.

Lastly,[18] I wish to speak of a little group of cases in children which possess several peculiar features, as the disease is always considered to be more serious in children than in adults. The group consists of two patients, a girl, aged 11, who has been under observation five years, and a girl, aged 10, who has been under observation two and a half years. The case reported by Porter Parkinson[19] may belong to this group. The two girls came to hospital chiefly because they had pruritus vulvæ. They are both very small for their age; a year ago they were both 4 inches under the average height and 11 lb. under the average weight for their age. One of them, E. B., has grown 3 inches in the last year, but the other one has grown ¼ inch only. The girl, E. B., had a sugar tolerance of about 50 g. of sugar in May, 1916, and of 70 g. in October, 1920. The girl, E. L., has a sugar tolerance of about 12 g. on a diet of 400 calories. The blood-sugar curves of this group of children are very interesting.

E. B. (Fig. 7).—A dose of 15 g. caused the blood sugar to rise from 0·16 g. to 0·29 g. in one hour, and it gradually fell in the course of the next two hours to 0·23 g. In the first two hours there was a trace of sugar in the urine, but it was too little to estimate with the polarimeter, and none at all in the third hour.

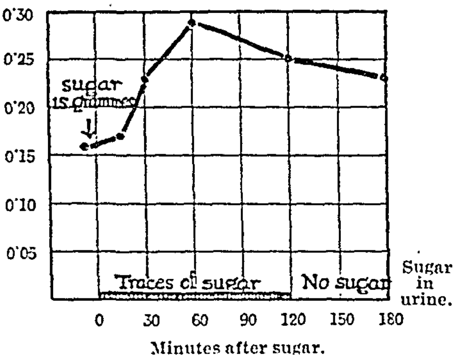

FIG. 7.—Showing effects of 15 g. sugar on level of blood sugar.

E. L.—On Nov. 7th, 1919, a dose of 10 g. of sugar caused the blood sugar to rise from 0·15 g. to 0·30 g. at the end of one hour, and at the end of three hours it was still at 0·23 g. In the first 90 minutes 1·5 g. were excreted in the urine, and in the next 90 minutes 1·1 g. (Fig. 8.) On July 13th, 1920, a dose of 10 g. of sugar raised the level of the blood sugar from 0·13 g. to 0·24 g. in one hour, and at the end of two hours it was still at 0·30. In the first hour 0·10 g. was excreted, in the second hour 0·15 g., and in the third hour 0·20 g. On Feb. 1st, 1921, a dose of 10 g. of sugar raised the level of the blood sugar from 0·145 g. to 0·26 g. in 90 minutes, and it had begun to fall after 120 minutes. Although the blood sugar did not rise so high or so rapidly, about 0·8 g. of sugar was excreted. The level of the leak-point seems, therefore, to have fallen somewhat.

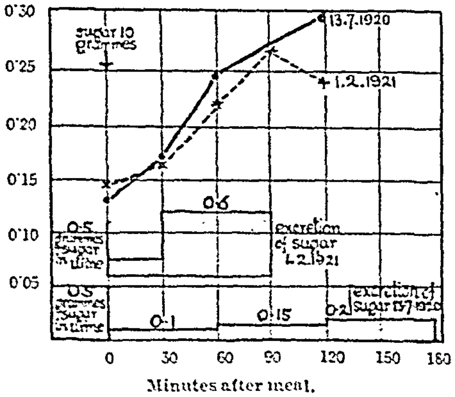

FIG. 8.—Showing effect of 10 g. sugar on level of blood sugar and amount of sugar excreted in urine on two given dates.

A consideration of these experiments shows that the dose of sugar causes a considerable and sustained rise in the blood sugar. On this evidence they must be considered as being true diabetics. It is clear also that the only reason these children do not pass more sugar is that the leak-point is usually considerably raised.

Raising of the Leak-point a Defensive Mechanism.

In 1915 I expressed the opinion that the raising of the leak-point must be in the nature of a defensive mechanism, and that is an opinion to which I still incline. The gradually increasing sugar tolerance in the case of E. B. may be due not to an increase in the power of the liver and muscles to store up sugar any more quickly from the circulating blood, but to the rise in the leak-point.

Allen[20] has considered this point in connexion with some of his dog experiments. He is strongly of the opinion that the raising of the leak-point is a disadvantage to the animal, as the internal secretion of the pancreas is being overworked whenever the level of the blood sugar is considerably raised. Williams[21] and Humphrey also think that the raising of the leak-point is a sign of evil import. Allen[22] has recently expressed the opinion that in some way the dogs were able to use the "extra" sugar which was in the blood with apparent benefit.

I am in complete agreement with Allen's views on the overtaxing of the internal secretion of the pancreas, but the course of the disease in these two children does not quite tally with his views about the high leak-point. One child has increased her sugar tolerance, and although the other one seems to remain stationary, she does not show any signs of dying. I must confess that I do not understand why the children continue to look so well.

This completes the account of the innocent types of diabetes and of those cases in which the change in the leak-point is an important factor.

Types of Diabetes Mellitus.

It has been the custom to divide the cases of diabetes mellitus into alimentary glycosuria and pancreatic diabetes. A study of the clinical picture shows that although a mild case of alimentary glycosuria differs greatly from a severe case of diabetes, yet cases occur of all degrees of severity, from the mild elderly glycosuria to the severe case whose duration of life after the onset of the disease may be a matter of days. Further, a study of the blood sugar in cases of alimentary glycosuria and severe diabetes does not suggest that there is any essential difference between the two types. In both the machine which regulates the taking up of sugar from the blood is out of action to a greater or less extent, and sugar floods the blood and is excreted in the urine. It seems to me better, therefore, to class all these cases under the head of true diabetes and to subdivide them into mild, medium, and severe types of the disease.

Mild type.—The mild cases usually, but by no means always, occur among elderly people; young people may also have a mild form of the disease.

The mild type is especially common among the natives of India and Ceylon. The patient, as a rule, does not at first complain of any symptom, and the sugar is often discovered accidentally in the course of a routine examination for life assurance, or for some other ailment. The amount of sugar excreted is usually small, 30–50 g., and is only excreted after a carbohydrate meal. The sugar may be present for one or two hours after the meal, and after that the urine may contain no sugar until the patient eats another meal which contains sufficient carbohydrates to overtax the sugar tolerance. The urine passed before breakfast usually contains no sugar. If these facts are considered in the light of our knowledge of blood sugar, it will be realised that the carbohydrates eaten at the meal raise the level of the blood sugar above the leak-point of the individual for a variable period, one, two, or three hours. During this period the sugar will be excreted in the urine until the level of the blood sugar falls below the leak-point. After that the extra sugar circulating in the blood will be gradually taken up and stored.

Many of the cases of mild diabetes occurring in elderly people are, in my opinion due to a temporary depression of the sugar mechanism by another illness. *The case of the elderly person who develops gangrene of one limb is typical* of this. Gangrene is so frequently accompanied by glycosuria that the surgeon always examines the urine carefully for sugar. So long as the leg remains in a damaged condition it may not be easy to keep the urine sugar-free, but once the leg has been amputated, always assuming that no sepsis or other complication occurs, the sugar usually disappears at once. The patient may recover quite a large sugar tolerance. The association of carbuncle and glycosuria is also well known. On this hypothesis there are a great many elderly people who are potential diabetics. That is, under ordinary circumstances they do not pass sugar on an ordinary diet, although their sugar tolerance is actually reduced. *When they are subjected to the additional strain of* an illness the sugar tolerance is so much reduced that sugar is excreted.

Medium type.—The medium type of case occurs more often among younger people, and in these cases the sugar is usually discovered because of the symptoms which the patient complains of.

He usually comes to the doctor complaining of weakness, lack of energy, pruritus, and thirst. The thirst in a medium case *is not a very prominent complaint and does not*, by itself, bring the patient to the doctor. He waits until after the other symptoms have appeared. That is, the medium case is very rarely seen quite early in the disease and the history is usually one of weeks or months.

The amount of sugar passed may be up to and over 100 g. of sugar, and when a patient of this type is investigated *sugar is found to be present in every specimen of urine* passed. The output of sugar per hour varies greatly, however, as there is an increase in the amount after each meal, and the urine passed before breakfast will contain least sugar. This, in terms of blood-sugar curves, means that the level of the blood sugar is always above the leak-point, although it varies with the amount of carbohydrate eaten at each meal. *It was formerly believed that the level* of the sugar in the blood was raised because there was a persistent call for the sugar on the part of the tissues which were, however, unable to use it. This hypothesis gains little support from the examination of blood-sugar curves. The effect of each dose of sugar in these cases is to raise the level of the blood sugar from an already high level to a yet higher level. *On the present hypothesis the sugar cannot be stored* by the liver and muscles and other depôts as well as before; consequently, the sugar circulates in the blood until the excess of it is excreted.

As I pointed out in the last lecture, the total sugar in the blood of a man of 10 st. 3 lb., or 65 kilos, is only 5 g. if the concentration of the sugar in the blood is 0·10 g. per cent. *It only needs an extra 5 g. in the blood to raise the percentage* of the blood sugar to 0·20 g. per cent., and of 10 g. to raise it to 0·30 g. per cent. These amounts are therefore very small in comparison with the amount usually eaten at a meal, and with the amount excreted by some diabetics. If these patients fast the level of the blood sugar usually drops below the leak-point at once, and may reach a normal figure. *When they are tested with a small dose* of sugar (10, 20, or 30 g.) there will be a rise and fall in the blood sugar from *0·12 to 0·20* and *down again, provided that the patients can* tolerate that dose of sugar. If the sugar tolerance is less than 10–20 g. the level of the blood sugar will rise above the leak-point and some sugar will be excreted. The patient therefore behaves just like a healthy person, but his tolerance *is reduced from*, say, 100 g. of sugar, to 10 or 20 g. The medium case will, of course, pass acetone bodies —aceto-acetic acid which is the dangerous substance, β-oxybutyric acid, and acetone.

Severe type.—The severe cases usually have an acute onset, though it must be remembered that any mild or medium case may become severe in course of time. Further, a mild or medium case may be converted suddenly into a severe one by any intervening disease such as influenza or septic infections.

The newly developed severe cases usually come to a doctor complaining of thirst, and if the case is very severe the actual day of onset can often be discovered. We have recently had three cases in which this could be done. One patient gave a six weeks' history of thirst and could fix the day of onset, having been very thirsty one evening in church and having had to get up twice that night to get water to drink. One boy of 17 gave a history of thirst of 17–20 days' duration. He was able to give the day approximately, as he was not thirsty on a Sunday, but was very thirsty on Thursday, *the early closing day of the week.* One boy, aged 10, gave a ten days' history, as he was not thirsty on the Sunday but was very thirsty on the Monday. This boy was the only one who complained of anything else at the onset. He was unwell with an indefinite malaise, and was kept in bed for three days after the onset. After that he went back to school, but was very easily tired. This boy *died on the fourteenth day after the onset of the thirst.*

Very acute cases of this type are rare, but may be commoner than is supposed.

Sir Archibald Garrod was once called out to see a young woman who had become unconscious that morning and had not complained of any illness before this day. The urine was examined, and a great deal of sugar and aceto-acetic acid was found. Dr. T. H. G. Shore tells me that he has made post-mortem *examinations on two soldiers who had died in* France of diabetes mellitus. One had died in the train on the way down from a C.C.S. to the base, and the other died *at a base hospital. In neither case had the disease been* recognised during life, but the bodies smelt so strongly of "acetone" that Dr. Shore examined the urine in the bladder, which was found to contain sugar and aceto-acetic acid in large amounts. *No other cause of death was found.* Even if allowance is made for the extreme degree of overwork which occurred at times in France it is difficult to avoid the conclusion that these two undiagnosed cases belong to the very severe and rapidly fatal type of the disease.

The symptoms which bring these patients to the doctor are usually thirst coupled with weakness or a feeling of tiredness. There is usually no malaise.

The sugar excreted in severe cases is large in amount—200 to 300 g. in the 24 hours—and is always present in the urine. In fact, the amount of sugar passed during the night hours may be as large or larger than that passed during the *day when the meals are eaten. The amount of sugar in the* blood is usually very high in these cases, and may be as much as 0·40 or even 0·60 g. per cent. The level of the blood sugar remains above the leak-point the whole of the day. If a dose of sugar be given to these cases in the form of a meal the level of the blood sugar rises rapidly after the meal *and then falls again.*

This is not quite the whole story, as the blood sugar at 6 A.M. was higher in one case than it was at 6 P.M., although nothing had been eaten for some hours. If these patients are starved the blood sugar usually decreases in amount, but it may take several days before it falls *below the level of the leak-point,* and longer still before it falls to the normal level for a healthy adult. The power of a severe diabetic to store sugar is exceedingly small, and a dose of 10 g. of sugar may be sufficient to cause the excretion of several grammes of sugar. (Fig. 9.)

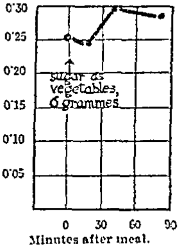

FIG. 9.—Effect of 6 g. sugar in vegetables on level of blood sugar.

Conclusion.

This completes my survey of the different types of diabetes mellitus. Many conditions may cause the presence of sugar in the urine, and the study of these is both fascinating and useful. If we are able to differentiate the cases into groups, and therefore to give a better considered prognosis, then we have at least achieved something. I am tempted to say that anything is better than the teaching of my student days—"death within two years whatever you do." It was not true then, and still less is it true now.

THE PREVENTION OF
URINARY OBSTRUCTION AFTER PROSTATECTOMY.[1]

BY J. W. THOMSON WALKER, M.B. EDIN., F.R.C.S. ENG.,

SENIOR UROLOGIST AND LECTURER ON UROLOGY, KING'S COLLEGE HOSPITAL; SURGEON TO ST. PETER'S HOSPITAL.

THIS article deals with fibrous contraction of the vesical outlet after suprapubic prostatectomy, and with an open operation for its prevention. No paper upon this subject should open without a reference to the fundamental work of our President, Sir Peter Freyer. I can look back to the time when castration, following the erroneous teaching of White, was in vogue as a cure for enlarged prostate, and when Harrison was attempting to prove by statistics that resecting the vas was an efficient substitute and would cure the condition.

I can thus appreciate more fully than many of you here the immense change that was brought about by the introduction of suprapubic prostatectomy by Sir Peter Freyer. It is therefore in no carping spirit of criticism of the operation of suprapubic prostatectomy that I bring forward those cases of post-operative obstruction, but with a view to discussing with you whether some modification of the original operation is not necessary in order to meet this sequel shown by experience to occur.

I shall first relate 16 cases of post-prostatectomy obstruction and then discuss them.

CASE 1.—R. T. H., aged 55 (Ref. No. 24). Examined Jan. 23rd, 1917. Prostatectomy Sept. 28th, 1916 (general surgeon). Prostate adherent and operation difficult. Fistula persisted. On Nov. 18th surgeon introduced forefinger into the bladder and pushed metal bougie through the closed internal meatus. Jan. 13th, 1917: Fistula still leaking, instruments passed under anæsthetic. On the 23rd urinary fistula through which all urine discharged; bougies arrested at internal meatus. Feb. 14th: Operation. Internal meatus admitted a small metal bougie and was surrounded by hard scar tissue. This was excised and a free opening into the prostatic cavity obtained. Wound healed satisfactorily and urine passed in good stream.

A year later the surgeon who had performed the original operation wrote to me about him as follows: "I saw a few days ago an old patient on whom I operated for enlarged prostate. I was pleased and surprised to see him so well, as when I last saw him there was great trouble from cicatricial contraction of the commencement of the urethra and I feared carcinoma. I congratulate you on a remarkable result."

CASE 2.—H., aged 71 (Ref. No. 29). Examined March 21st, 1918. Prostatectomy Jan. 14th, 1918 (general surgeon). Prostate large and shelled out in one piece. Difficulty in separation on left side and posteriorly. Emphysema, bronchitis, dilated heart, and glycosuria. Three weeks after operation attempts to pass catheter failed. Feb. 17th: Instruments passed with finger in bladder and catheter tied in for 14 days. March 21st: Urine discharged entirely by suprapubic fistula, metal instrument arrested at entrance into the bladder. Bladder opened freely, internal meatus completely closed by thick membrane. Membrane excised and large opening into prostatic cavity obtained. A month later suprapubic wound healed and urine passed naturally.

Three months after operation patient died of cardiac failure, having continued to void urine naturally.

CASE 3.—P. W., aged 64 (Ref. No. 35). Examined April 15th, 1918. Prostatectomy Nov. 3rd, 1917 (urinary surgeon). Difficulty in enucleation at lower part of prostate. After operation increasing difficulty in passing catheters. Fistula persisted and urine passed partly by urethra. February, 1918: Surgeon opened bladder and tied catheter in urethra. Wound healed but repeatedly broke down again. There was difficult micturition and attacks of retention. A catheter was obstructed at the internal meatus. At night urine passed only by catheter. April 29th, 1918: Bladder opened freely; vesico-prostatic opening was a small aperture surrounded by a thick cuff of fibrous tissue which gripped a fine catheter tightly. Fibrous tissue removed and prostatic cavity exposed. July: Wound closed, micturition normal.

CASE 4.—A. W. W., aged 65 (Ref. No. 35). Examined Nov. 4th, 1918. Prostatectomy November, 1917 (general surgeon). Since operation frequent micturition day and night and intense desire and spasm. Catheter passed occasionally with difficulty 8 inches from meatus.

On rectal examination a hollow in region of prostate with some thickening on either side. On cystoscopy outline of internal meatus very irregular, a diverticulum at bladder base. Nov. 20th, 1918: Bladder opened, a pea-sized nodule of gland tissue at posterior lip of internal meatus. Internal meatus surrounded by fibrous ring; diverticulum with capacity of bean. Nodule removed and large opening into prostatic cavity obtained by cutting away fibrous ring; diverticulum excised. October, 1919: He reported "result of operation splendid and water passed very easily."

CASE 5.—W. M., aged 60 (Ref. No. 33). Examined Feb. 13th, 1919. Prostate removed September, 1918 (general surgeon). Prostate large and operation straightforward. Fistula persisted and healed up for short periods. Difficult micturition, sometimes performed only in recumbent position; dribbling at end of act. Metal instruments passed regularly but with difficulty. Rectal examination showed hollow area in prostatic region and no sign of malignant infiltration. February, 1919: The surgeon again operated, but failed to reach the obstruction and could not pass an instrument through the urethra.

May: I exposed the bladder and found internal meatus surrounded by hard fibrous tissue. This was cut away and a free opening obtained; the wound healed satisfactorily, the bladder closed, and patient was able to pass water freely.

CASE 6.—A. H., aged 53 (Ref. No. P. 246). Examined July 8th, 1920. Prostatectomy March, 1920 (urinary surgeon). Wound healed. Two weeks after returning home difficulty of micturition recommenced, and finally no instrument could be introduced into bladder, obstruction being at internal meatus.

Operation July 12th, 1920. Internal meatus surrounded by scar tissue and admitted probe. Scar tissue cut away; irregular areas of fibrous tissue in wall of prostatic cavity, and in dissecting a fibrous mass a portion of the rectal wall was excised. Edges of rectal wound brought together with catgut stitches, catheter tied in urethra and prostatic cavity packed with iodoform gauze. Continuous irrigation of bladder and prostatic cavity, and frequent rectal washing. Wounds healed, and patient left hospital passing clear acid urine freely.

CASE 7.—A. F. H., aged 63 (Ref. No. 46). Examined Oct. 11th, 1920. May, 1918, prostatectomy (general surgeon with special experience). Moderately enlarged firm prostate. After operation great difficulty in passing instruments. Urethra dilated with metal instruments. Fistula persisted in spite of retained catheter. For 18 months urine passed only in a dribble, and has been on catheter life. Fistula closes for some weeks and then reopens. Micturition ceases after passing an ounce of urine and then catheter withdraws about a pint. In rectum a hollow prostatic area without induration. Small catheter passed but was gripped at internal meatus.

Operation Oct. 21st, 1920. Masses of fibrous tissue removed and bladder mobilised. Neck of bladder and internal meatus drawn under arch of pubes and fixed with fibrous tissue. Mucous membrane at internal meatus fell together laterally so as to close it. With finger no opening felt. On introducing catheter the internal meatus was found to be an antero-posterior slit, surrounded by hard, fibrous tissue, which gripped the point of the catheter. Fibrous ring was dissected away and free entrance to prostatic cavity obtained. Small fistula persisted for some weeks, but eventually healed. There was a full and powerful stream and no residual urine.

CASE 8.—E., aged 63 (Ref. No. 48). Examined Oct. 27th, 1920. October, 1918, prostatectomy (urinary surgeon). Enlarged prostate and some calculi removed. During convalescence difficulty in passing urine and instruments were passed. After leaving the home obstruction increased, and in March, 1919, catheter passed with difficulty. April, 1919: Complete retention. Instruments failed. A general surgeon opened bladder and introduced catheter. After that much better, but had to use catheter frequently. Difficulty of micturition increased, and in June, 1920, instruments were passed twice. Dilatation was followed by increased difficulty and retention, requiring catheter. During September and October, 1920, there were repeated attacks of retention of urine, relieved by dilatation by bougies and passage of catheter. I examined him on Oct. 27th, 1920. He was confined to bed and in a nervous, depressed condition, with tremors of hands and legs. Bladder not distended; in rectum there was a hollow prostatic area; no dilatation of seminal vesicles and no induration. Metal catheter (No. 8) passed an obstruction at the membranous urethra and another at entrance into bladder, where it was tightly gripped.

I operated on Nov. 4th, 1920. Large hernia of suprapubic scar. Lower part of bladder and internal meatus were dragged down under the pubic arch by fibrous tissue and were very difficult to reach. Internal meatus was a rigid ring admitting tip of little finger. A quarter of an inch below this the catheter lay in hard ring of fibrous tissue. Fibrous tissue at internal meatus and in prostatic cavity was dissected away. Anterior wall of prostatic cavity also dissected away from pubic symphysis.

Patient returned home five weeks after operation. Urine was then passed freely with good stream but with some lack of force. Catheter passed easily into bladder; no residual urine. At times there is an escape of a few drops of urine on rising suddenly or on sitting up in bed, but this symptom now (March, 1921) occurs at long intervals.

CASE 9.—W. S., aged 55 (Ref. No. P. 387). Examined Nov. 4th, 1920. Prostatectomy June, 1920 (general practitioner). After operation never passed urine by urethra except with catheter; urinary fistula persisted, instruments being arrested at internal meatus. Prostatic area soft, no induration.

Operation Nov. 8th, 1920. Scar excised, bladder base exposed; internal meatus found to be completely closed; tongue of tissue about size and shape of bean and free at one end projected upwards from the bladder base in position of internal meatus. This mass was cut away and mucous membrane and fibrous tissue forming roof to prostatic cavity removed, and free opening made. The patient made uninterrupted recovery, and left hospital healed and passing urine freely in powerful stream.

CASE 10.—A. D., aged 60. Examined Jan. 13th, 1921. Prostatectomy Sept. 11th, 1920 (general surgeon). Prostate removed with difficulty in two pieces. Very adherent posteriorly. Catheters passed during convalescence. Healed in nine weeks, but broke down again and has since healed and broken down several times. Metal instruments were passed. Urine passed with difficulty; micturition easier lying on back. Residual urine varied from six to nine ounces.

Operation Jan. 19th, 1921. Thick masses of scar tissue dissected from suprapubic area and bladder freely opened. Internal meatus admitted tip of little finger, and was filled with soft granulation tissue. About a quarter of an inch below internal meatus prostatic cavity narrowed by fibrous tissue which reduced lumen to No. 6 English bougie. Fibrous tissue was dissected away and found to extend down to triangular ligament where opening was small and rigid. Catheter was tied in; recovery was complete, with free and powerful stream.

---

[1] A paper read before the Section of Urology of the Royal Society of Medicine on Jan. 27th, 1921.

CASE 11.—R. S., aged 60 (Ref. No. 18). Examined June 15th, 1914. Prostatectomy March 4th, 1914 (general surgeon). Operation difficult; prostate hard and fibrous; no irrigation of bladder during convalescence. First time catheter was passed a gush of pus came away, but no urine. Many unsuccessful attempts were made to pass instruments into the bladder. Suprapubic fistula persisted, and all urine discharged through this. On examination skin of lower abdomen eczematous; suprapubic scar thick and indurated. All urine was discharged through fistula. Obstruction to instruments after passing membranous urethra, and between this and the bladder there was an area of hard fibrous tissue. Metal instruments passed up to 16/18 English and a catheter tied in urethra. In 14 days suprapubic wound healed and eczema disappeared. Urine passed freely by urethra. Patient died suddenly four months after I saw him after obscure abdominal symptoms. Intestinal obstruction was found, due to a band extending from upper part of right side of bladder down into pelvis.

CASE 12.—C. H., aged 61 (Ref. No. 16). Examined April 6th, 1914. Prostatectomy (general practitioner), January, 1914. Suprapubic tube retained for 14 days after operation. Fistula persisted, only a few drops of urine being discharged from urethra and a stream from fistula. Obstruction at vesico-prostatic junction, which admitted small instrument. *On rectal examination a hollow area* was found in place of prostate and no induration. Catheter tied in and suprapubic wound healed, but there was constantly recurring difficulty of micturition and instruments were passed at intervals. He lived in the country, and finally was able to pass instruments himself and keep the scar dilated.

CASE 13.—S. W., aged 58 (Ref. No. 14). Examined March 17th, 1914. Prostatectomy Oct. 23rd, 1913 (urinary surgeon); simple adenoma. Great difficulty in passing catheter three weeks after operation. Patient left the home Nov. 30th healed and passing fairly good stream, which got gradually worse and at end of December was reduced to a mere dribble. Surgeon again attempted to pass catheter and failed. Patient was told that there was block at neck of bladder. When I examined him urine was passed in feeble dribbling stream. In the rectum there was a hollow area in place of prostate, but no induration. In passing instrument there was difficulty at membranous urethra and also at internal meatus and I *failed to enter bladder. Operation for removal of obstruction* recommended, but I did not see patient again.

CASE 14.—W. P., aged 75 (Ref. No. 34). Examined Dec. 12th, 1918. *Prostate removed (urinary surgeon). Prostate large and shelled out* easily. Wound closed, but in a few months he had increasing difficulty in micturition and required catheter. In March, 1916, bladder was opened and internal meatus dilated; the wound healed quickly. When I examined him he complained of frequent micturition, and passed a small dribbling stream after great difficulty. I failed to pass an instrument into the bladder, the obstruction being at the internal meatus. Fibrous thickening in prostatic *area was felt from rectum.*

On Dec. 18th, under spinal anæsthesia, instruments passed and a catheter tied in urethra. The obstruction slowly recurred, and on March 20th, 1919, I again passed instruments.

CASE 15.—W. G., aged 77 (Ref. No. 33). Examined Oct. 5th, 1918. Prostatectomy five years before (general practitioner). Prostate weighed 11¼ ounces. For some months before I saw him he had increasing difficulties of micturition and frequency of straining. Prostatic area flat and no sign of malignant infiltration. I failed to pass instruments, the obstruction being at the internal meatus. Under an anæsthetic the fibrous ring was dilated and a catheter tied in. *Micturition was free for a time*, but on Nov. 29th, 1918, the obstruction at the internal meatus had again developed. Urethra dilated and a catheter tied in. I have lost sight of this patient.

CASE 16.—R. S. R., aged 58 (Ref. No. 49). Examined Dec. 1st, 1920. Prostatectomy May, 1919 (urinary surgeon). Previous to operation was on catheter life. Operation said to be difficult, but no information in regard to prostate; wound healed in four weeks. Had bilateral epididymitis. Since operation patient can pass one ounce of urine voluntarily and then requires catheter. *He had undergone* a course of electric treatment for the bladder since the operation. *On examination the bladder was distended. The prostatic area* was hollow and without induration. A small catheter passed with difficulty, being gripped in prostatic area. Two pints of stinking alkaline urine were withdrawn. No sign of disease of the nervous system and no history of syphilis. I did not consider that there was nerve atony of the bladder, but regarded the condition as one of obstruction at the internal meatus. Cystoscopy recommended, but patient refused.

DISCUSSION OF CASES.

These 16 cases are patients suffering from obstruction after suprapubic prostatectomy, *the obstruction being due to the formation of fibrous tissue in the* area from which the prostate was removed. The cases have been carefully selected so as to exclude two types of case in which there is post-prostatectomy obstruction, but which for the sake of clearness I am anxious to exclude from discussion at present. These types are:—

(1) Obstruction due to prostatic lobes left behind at the operation. I have seen a few cases where a large part of the prostate, amounting to a whole lobe, or even *what would* appear to be both lobes, was discovered in examining for the cause of the obstruction after a so-called prostatectomy. Freyer has published such cases.

(2) Obstruction due to malignant growth following the *removal* of a prostate. This includes cases *frankly malignant* at the time of the operation, cases where there was a suspicion of malignancy, and the difficulty in enucleation and eventually the microscope proved that malignant change had occurred in a simple enlargement of the prostate, and finally, cases where clinically there was a simple enlargement, *but the pathologist reported that some part of the* adenomatous prostate showed malignant changes.

All *these types I have excluded from this* article as they raise issues outside those I wish here to discuss. Further, I wish to make it clear that there are here no cases of atony of the bladder from disease of the spinal cord, or atony of the bladder of the type I have described as atony without obstruction or signs of nervous disease. The tone of the bladder in these cases was normal and capable of projecting a good stream of urine when the obstruction was removed.

Post-Operative History.

The post-operative history of these cases is of interest. In some the obstruction appeared early in the convalescence from the operation. There was a delay in passing urine, and instruments were passed usually about three weeks after the operation in order to dilate the urethra and assist the passage of urine. In other cases there was difficulty in passing a catheter *from an early date after the operation, and a catheter* was tied in. In spite of these precautions obstruction commenced either at once or soon after leaving the home. In one case the obstruction became evident some months after the operation and in another only four years after the operation. In two cases no urine was passed at any time after the operation, and all attempts to pass instruments into the bladder failed. These two patients were told that the condition was incurable, and the suprapubic fistula must remain open. A suprapubic fistula persisted in 8 of the 16 patients and in 4 of these all the urine was passed through the fistula, no urine passing by the urethra. In the *remaining 4 cases some* urine passed by the urethra and some by the fistula. In two of these (Cases 5 and 7), the fistula healed up from time to time and then broke down again.

In cases where the wound healed completely or the fistula only broke down occasionally the symptoms were those of severe obstruction, usually constant, but occasionally varying from difficult micturition and straining to periods of retention. In such cases the *patient was on catheter life, the catheter being* passed with great difficulty. In three cases after some months instruments were passed under an anæsthetic and the stricture dilated, this proceeding being repeated on several occasions. In four cases a second operation had been undertaken, the bladder being opened, instruments being passed, and a catheter tied in the urethra. In all of them the obstruction had recurred.

Anatomy of the Prostatic Bed after Prostatectomy.

In order to understand the condition present in these cases *it is necessary* to have a clear idea of the anatomy of the parts after prostatectomy. The enlarging prostate expands in two directions: (1) backwards towards the rectum, expanding the fascial sheath and stripping it from the bladder base; and (2) upwards into the bladder, stretching the sphincter and pushing up through it into the bladder cavity.

After enucleation of the prostate a cavity of varying size is left. Lying on the postero-inferior wall of this is a small strip of the mucous membrane of the urethra, representing the portion of the posterior wall of the prostatic urethra which *lies between the* verumontanum and the membranous urethra. *(Fig. I., 1 and 2.)* The seminal vesicles lie in the posterior wall, having been stripped from the bladder base by the enlarging prostate. This cavity is roofed by a shelf or canopy formed by the bladder base, and communicates with the bladder cavity by the opening through which the prostate was *enucleated*. This opening varies very greatly in size.

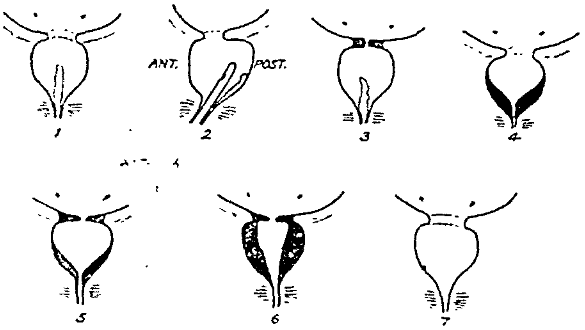
In prostates where the intravesical projection of the prostate has been very large, the opening may be so wide that there is scarcely any ledge at all. In the majority of prostates, however, this ledge is very pronounced, and the *opening* into the vesical cavity lies at the anterior part of the *roof of the prostatic* bed. This is most evident in the type of prostate where the enlargement has been extravesical and can be felt prominently in the rectum, but does not project through the sphincter into the bladder, and in those prostates where there is a small intravesical nodule and a large extravesical adenomatous mass. At this prostato-vesical opening the mucous membrane of the urethra, when it joins that of the bladder, is torn across.

The urethra communicates with the prostatic cavity at the lower end and anterior part, this part of the urethra being directed obliquely upwards and backwards. The mucous membrane of the urethra is usually torn across very obliquely at the prostato-urethral junction. The anterior wall is torn at or near the point where the membranous urethra joins the prostatic cavity, a strip of the posterior wall of the prostatic urethra extending as high as the verumontanum is usually left behind, adhering to the posterior wall of the prostatic bed. On examining specimens of the enucleated prostate, when the gland has been removed in a mass, the absence of this strip of the posterior wall of the prostatic urethra will be noted. In some cases a large part of the prostatic urethra remains as a long ragged tube attached to the membranous urethra, in other cases a long tube of the mucous membrane of the membranous urethra is removed with the prostate. These conditions are, however, exceptional, and the common condition is as I have noted.

Anatomy of Post-Operative Contraction.

It is many years since I showed[2] that there were two danger points for the development of stricture after prostatectomy—namely, at the membranous urethra when the mucous membrane is severed, and at the outlet of the bladder when the mucosa of the bladder neck is torn across. It is rare to find any contraction at the membranous urethra, partly because it is the custom to pass the catheter in order to wash the bladder during convalescence; if there is any obstruction here it will at once be noticed, and catheters of different calibres passed through it. But the principal reason for the absence of contraction at this point is, I believe, to be found in the strip of mucous membrane which almost always remains attached to the posterior wall of the prostatic bed. This strip prevents the formation of a circular ring of fibrous tissue, which might develop if the mucous membrane were torn across transversely.

FIG. I.—*Prostatic Cavity after Suprapubic Prostatectomy.*



1. Coronal section showing prostato-vesical opening (dotted lines), strip of prostatic urethra on posterior wall, compressor urethral muscle.
2. Sagittal section with catheter showing posterior ledge.
3. Fibrous contraction at prostato-vesical opening.
4. Fibrous contraction at prostato-urethral outlet.
5. Fibrous contraction at both outlets.
6. Fibrous tissue in wall of cavity.
7. Prostatic cavity after removal of fibrous masses.

In some cases where a sleeve of mucous membrane of the membranous urethra is removed with the prostate there is certainly a tendency to contraction of the scar in the region of the triangular ligament. In these 16 cases there are only 2 where the obstruction was very pronounced at the urethral end of the prostatic cavity. It is at the inlet of the prostatic cavity into the bladder that the contraction may take place, and obstruction at this part was present in 14 out of the 16 cases here recorded. (Fig. I., 3.)

In 10 of the 16 cases I operated, opening the bladder freely and inspecting the prostato-vesical opening. In 4 of the cases the obstruction was physiologically complete, all the urine passing through a suprapubic fistula. In the remaining 12 the obstruction was incomplete. There were two cases where the internal meatus was completely closed, no trace of an opening being discovered either by palpation or by inspection. In one of these (Case 2) the base of the bladder was smooth and there was no indication as to where the opening into the prostatic cavity had been. In the other case (Case 9) the opening was obliterated, but just behind its probable position, judged by pushing up the roof of the prostatic cavity from below with a metal sound, a tongue-shaped nodule of prostatic tissue, the size of the terminal joint of the thumb, projected upwards and forwards. This tongue of prostatic tissue was attached by a comparatively narrow base, and had evidently been a nodule which was partly detached at the time of the operation, but had retained a sufficient blood-supply to survive. Had an opening into the prostatic cavity been present it would have acted as a valve. In the two remaining cases, where the obstruction to the passage of urine was complete and the introduction of a catheter was impossible, the internal meatus was so small that only a fine probe could be passed through it from the bladder into the prostatic cavity (Cases 1 and 6).

In two cases a fine catheter could be passed with great difficulty. In one the catheter was found at operation to be firmly gripped by a ring of fibrous tissue (Case 3). In the second (Case 8) the internal meatus was fibrous but open, and admitted the tip of the forefinger. Below this, near the apex of the prostatic cavity, there was a dense mass of fibrous tissue which caused the obstruction. This on dissection was proved to extend to the membranous urethra. (Fig. I., 4.)

In three cases a No. 8 catheter could be passed after some difficulty, and at operation there was a fibrous ring which held the catheter in a firm grip (Cases 4, 5, and 7). In one of these, in addition to the fibrous ring, there was a small nodule of prostatic tissue on the posterior lip of the opening, and also a diverticulum of moderate size (Case 4). In another, on removing the catheter the fibrous sides of the ring came together and formed a narrow antero-posterior slit.

In all the cases complete restoration of the bladder function with free flow of urine followed the operation and the fistula healed.

Possible Causes for Failure of the Operation.

Before passing on to consider the treatment of these cases and the method of prevention, two points will be considered.

(1) Is the post-operative obstruction in these cases due to inexperience or lack of skill on the part of the operator?

In the cases here recorded we find that three were operated on by general practitioners, six by general surgeons, one by a general surgeon with special urinary experience, and six by urinary surgeons. I do not wish to give the impression that although the cases are practically divided between the general surgeons and the urinary surgeons, these two types of operator are specially responsible for the result, for it must be obvious to anyone that the general surgeon operates on a much greater number of cases of enlarged prostate than the general practitioner, and it is a fact that the urinary surgeon operates on more cases of enlarged prostate than the general surgeon. The true proportion could only be reached by taking the percentage of the results of all cases operated on by each class, a figure impossible to state. What I think these figures show is, however, that post-operative obstruction of this nature may, and does, occur in the hands of the most experienced class of operators on the prostate. I draw the inference from this that, although lack of skill might have been shown in one or two cases, the operation may be skilfully carried out and still, in a certain number of cases, be followed by obstruction of this special kind.

(2) The second point to which attention will, I think, be directed is the question as to whether the type of prostatic enlargement may have some influence on the result.

I have already made clear that all cases of malignant growth have been excluded from these records. There remain two types of prostatic enlargement, the extreme examples of which differ materially from each other, the small fibrous or fibro-adenomatous type and the large prostatic adenoma. Broadly speaking, the small fibrous or fibro-adenomatous type is enucleated with difficulty and leaves a small cavity, while the large adenoma shells easily and leaves a large cavity. There has been some difficulty in discovering what type of prostate was removed in these 16 cases and in 5 cases I have no information. In the remaining 11 cases 5 were known to be small and fibrous and 6 were adenomatous, 5 being designated "large adenoma" and one "simple adenoma." I do not consider these figures are conclusive, one-third of the cases being excluded.

I have the impression, gained from some years' experience of open inspection of the prostatic cavity and internal meatus during prostatectomy, that the condition likely to produce post-operative obstruction by contraction of fibrous tissue is more frequently present in operation on the fibrous or fibro-adenomatous prostate than on the large adenomatous

---

[2] Brit. Med. Jour., 1905, ii., 1250.

—that is to say, where the size of the prostato-vesical aperture is small. In the adenomatous prostate there are frequently found long loose strips of capsule or of the anterior commissure, semi-detached nodules or prostatic tissue, or loose strips of torn urethra.

I have fully discussed and illustrated these strips, flaps, and nodules elsewhere,[3] and shall refer to them again in discussing the operation. But the fact that in six of these cases the prostate was stated to be adenomatous (five being large adenomas) shows quite clearly that fibrous contraction of the bladder outlet may occur after operation on this type of prostatic enlargement, as well as after that on the fibrous prostate.

Treatment of Post-operative Obstruction.

I will first discuss the treatment of obstruction when it has actually occurred and then turn to my proposal for prevention. It is, I believe, the routine custom with most surgeons in this country to pass a catheter daily after the operation and wash the bladder, commencing with the catheter about a week after the operation and continuing until the suprapubic wound is healed. The first evidence of obstruction is difficulty in passing the catheter, and there is delay in the healing of the wound. The wound may, however, heal up either in average time or after some delay. A fistula persisted in 8 out of the 15 cases here recorded.

The difficulty of passing a catheter into the bladder after many cases of prostatectomy is, I think, pretty generally recognised; it is due to the catheter hitching under the ledge over the posterior part of the prostatic cavity found by the bladder base, and is surmounted by using a fully curved catheter and keeping well forward, when the instrument slips easily into the bladder. The obstruction to the passage of instruments, where there is narrowing at the internal meatus, is of similar character, but either the instrument entirely fails to enter the bladder after the whole of the roof of the prostatic cavity has been searched, or it enters the bladder and is felt to be gripped in a stricture.

In most cases of this series this has been the signal for an attempt to dilate up the internal meatus by the passage of instruments, and if the attempt was successful a catheter was tied in for a time. This treatment was adopted during the early part of convalescence after operation in several of the cases here recorded. Where it failed the forefinger was passed along the still open wound and metal instruments guided through the internal meatus or forced through the almost closed aperture. This was carried out in two of these cases. In some instances this treatment was not successful, and the obstruction either progressively increased or recurred after a time. Now either a catheter was passed constantly with difficulty, or regular or recurrent dilatation was carried out, or instruments failed altogether. When the obstruction had reached this stage either the patient was abandoned to a life of misery with a suprapubic fistula or a second operation had been performed. In four cases secondary operations had been performed at intervals of from four to ten months after the operation. These secondary operations consisted of opening the bladder, forcing a metal instrument through into the bladder from the prostatic cavity, and tying in a catheter for a varying time. In all these cases the obstruction recurred after a comparatively short interval.

I saw these patients at a time varying for two months to five years after the prostate had been removed. Four of them I treated by dilatation with metal instruments under an anæsthetic, and this was repeated several times in some cases. The contraction was temporarily relieved, but in none was a permanent cure effected. One patient learned to pass a bougie himself and used the instrument regularly; the others after one or several dilatations passed out of my care.

Dilatation in these cases is, I consider, an unsatisfactory method and gives only temporary relief. The condition is a traumatic stricture, and resembles a traumatic stricture in the bulbous urethra in the difficulty in treatment by dilatation. Moreover, the passage of instruments is usually attended with much difficulty, owing to the presence of the prostatic cavity in front of the stricture. In ten cases I operated and removed the scar tissue through a suprapubic wound.

The following points are essential in carrying out the operations:—

(1) All scar tissue in the abdominal wall is removed and the bladder separated from the abdominal wall.

(2) The bladder is dissected from the posterior aspect of the pubic symphysis, and mobilised.

(3) With the patient in the Trendelenburg position the base of the bladder is freely exposed by means of retractors.

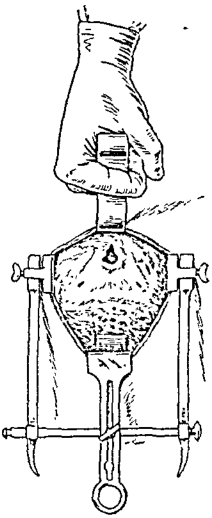
(4) In the cases where a catheter can be passed through the internal meatus, it is necessary to withdraw this before attempting to excise the fibrous ring. The ring is grasped with long forceps and cut backwards with long curved scissors. The scar tissue on each side is then dissected away so that a free opening is obtained. (Fig. I., 7.) Where the internal meatus is completely closed a metal instrument should be passed along the urethra and the roof of the prostatic cavity pushed up on the point of the instrument and incised. The whole of this canopy is then dissected away. Dissection may have to be carried into the prostatic cavity, for in some cases thick ridges of fibrous tissue may be found on the wall. (Fig. I., 5 and 6.) Great care must be exercised here. The rectum lies immediately beneath and is adherent. In one case, when dissecting away a mass of fibrous tissue, I excised a strip of the rectal wall. Stitches were introduced and irrigation of the prostatic cavity and rectum carefully carried out and the wound healed, the patient leaving hospital with a clean sterile urine. This case shows the danger of too free dissection inside the prostatic cavity.

Where the obstruction lies in the neighbourhood of the membranous urethra the dissection is extremely difficult owing to the fact that the scar tissue round this part drags the urethra under the arch of the pubes, and even with a perfect exposure of the bladder base and prostatic cavity it is difficult to reach this area. I have not found it necessary after the free opening up of the prostatic cavity to tie in a catheter unless it is desired to treat concurrent sepsis by constant irrigation.

An Open Operation for the Prevention of Post-prostatectomy Obstruction.

The operation consists in first enucleating the prostate and then in freely exposing the bladder base and prostato-vesical opening by means of the Trendelenburg position and special retractors. Any fold or flap that might cause obstruction is then removed. The details of the operation are as follows:—

FIG. II.



Exposure of bladder base and prostato-vesical opening after enucleation of the prostate.

A catheter is passed and the bladder distended with 12 or 14 ounces of fluid. A free suprapubic incision is made, the bladder is opened, and the prostate is enucleated with the gloved right forefinger. I can in most cases dispense with the finger in the rectum, but in small tough or in very large prostates the gloved forefinger is used to push up the prostate from the rectum. The prostate being free in the bladder, the left forefinger is removed from the rectum; the glove is stripped from the left hand by a nurse and replaced by a fresh glove. The prostate is then removed from the bladder by means of forceps, aided with the left forefinger.

So far, except for the matter of gloves and the avoidance in many cases of the introduction of a finger into the rectum, the operation is that practised by Freyer. Now we depart from his technique. Instead of irrigating the bladder with hot solution, a catgut stitch is passed through each lip of the bladder wound and the patient is placed in the full Trendelenburg position. A good headlamp is essential for this part of the operation.

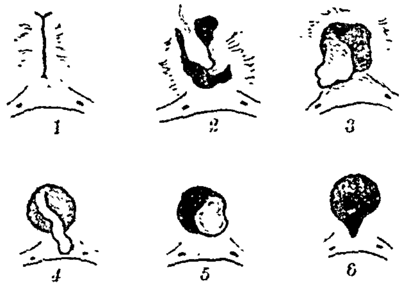
I then introduce my bladder retractors and freely expose the base of the bladder and the prostato-vesical opening. (Fig. II.) A gauze plug is pushed into the prostatic cavity to control bleeding temporarily and the bladder is emptied of clot. When this is done the plug is removed, and a careful inspection of the prostatic cavity and its inlet into the bladder is made. Hæmorrhage first claims attention. In some cases, by the position of the patient and the temporary plugging the hæmorrhage is already reduced to a very small amount of venous oozing. In most cases, however, some amount of bleeding is in progress and in some spouting arteries are seen.

---

[3] British Journal of Surgery, 1920, No. 28, vol. vii.

The bleeding is of two kinds, arterial and venous. Arterial bleeding comes in many cases from an artery situated at the brim of the vesico-prostatic entrance on one or both sides. There is frequently a spouting vessel on each side in this position, just below the mucous membrane. Long Spencer Wells forceps are placed on these vessels. With my handled bladder needle, a catgut stitch is passed on each side through the edge of the mucous membrane of the bladder and the sphincter and tied anterior to the forceps. Care must be taken not to pass these stitch ligatures too deeply, for the *prostatic plexus of veins runs horizontally in the angle just* outside this on each side. These two sutures now act as tractors to pull up the neck of the prostatic cavity and keep the edges apart. Arterial bleeding from the wall of the cavity may be seen, and Moynihan's rather heavy artery forceps with curved beak are applied and the tissue in their grasp crushed. Venous bleeding comes mostly from the anterior wall of the cavity in which lies the vertical limb of the prostatic plexus. It is difficult to see the bleeding point here, but in most cases it is not serious and may be controlled by a temporary plug. In cases where the bleeding is unusually severe plugging with iodoform gauze will efficiently control it; this is very accurately carried out with the cavity freely exposed. The point of the catheter is pulled well into the bladder and strips of gauze packed into the prostatic cavity round this, the gauze being removed on the second day.

FIG. III.—*Internal Meatus after Prostatectomy.*



1. Lateral folds of mucous membrane closing internal meatus.
2. Flaps of mucous membrane.
3. Adherent flap of prostatic capsule.
4. Strip of prostatic urethra.
5. Adherent nodule of prostate.
6. Flaps removed and wedge of posterior fold excised.

Having controlled the hæmorrhage, the next point to attend to is the removal of any structure that might produce post-operative obstruction. A large variety of tags, flaps, strips, nodules, or folds are found. It is a revelation when one comes to examine the prostatic cavity after enucleation of the prostate to see the number, size, and variety of these loose masses of tissue.

I have described elsewhere the following:—

1. Strips of mucous membrane at the prostato-vesical opening. (Fig. III., 2.)
2. Nodules of prostatic tissue in the neighbourhood of the opening. These may be present even where the prostate has apparently shelled out cleanly.
3. Loose strips of prostatic capsule and occasionally small nodules of gland tissue attached loosely to the wall of the prostatic cavity. (Fig. III., 3, 5.)
4. Loose strips of urethral wall pulled out and torn across. (Fig. III., 4.)
5. Flaps of mucous membrane. At the *prostato-vesical* opening there is frequently a large loose flap of mucous membrane on each side, and these flaps may almost meet over the prostatic cavity. (Fig. III., 1.)
6. A prominent semilunar ridge forms the posterior lip of the opening. This ledge is formed by the trigone and adjoins the base of the bladder.

It is to the last two structures that I wish specially to direct your attention at present, *for they are the* cause of the permanent obstruction. These flaps of mucous membrane may unite so as completely to close the prostato vesical orifice and the crescentic fold is the structure that promotes the narrowing by fibrous contraction after the operation. The flaps of mucous membrane are dissected away; the posterior fold is grasped in long forceps, and a wedge with the base anterior is cut out of it with curved scissors. (Fig. III., 6.) The tissue removed consists of mucous membrane, trigonal muscle, *and frequently some gland tissue. This* effectually removes any possibility of narrowing at the prostato-vesical opening.

It may be objected that this free enlargement of the prostato-vesical opening destroys the vesical sphincter. In 1904 I pointed out that the action of the internal vesical sphincter was destroyed in cases of suprapubic prostatectomy from enlarged prostate. The sphincter action is taken up by the compressor urethræ, which effectually prevents the escape of urine. The prostatic cavity thus forms a prolonged neck communicating with the bladder cavity.

Having completed *the clearing out of the prostatic* cavity and the enlarging of the prostato-vesical opening, repair of the bladder and abdominal wall is undertaken. The retractor is removed from the bladder and the bladder blades replaced by the abdominal blades. By inserting it so as to retract the abdominal wall with the frame to the kneeward side of the operation field the anterior wall of the bladder is fully exposed. A large rubber tube is placed in the bladder and the catgut slings are crossed in front of this so that the edges of the cystotomy opening are brought together. Interrupted catgut sutures are placed in this, the slings are removed, and the bladder drops down into the pelvis. A small rubber tube is placed in the prevesical space. Two catgut mattress sutures are placed through the recti and sheath about an inch on each side of the wound, and the margin of the anterior rectus sheath are united with a continuous catgut suture.

A CONTRIBUTION TO THE

STUDY OF THE ENDOTHELIOMATA.

BY E. H. KETTLE, M.D., B.S. LOND.,
PATHOLOGIST TO ST. MARY'S HOSPITAL;
AND
JOAN M. ROSS, M.R.C.S., L.R.C.P. LOND.,
RESEARCH STUDENT.

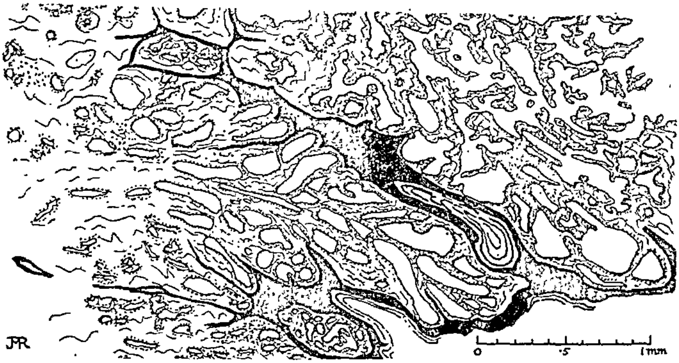
(From the Department of General and Special Pathology, Institute of Pathology and Medical Research, St. Mary's Hospital.)

NO one will dispute the statement *that there* is less unanimity among pathologists on the subject of the endotheliomata than there is about any other type of tumour. Every standard text-book of pathology bears witness to this, and in all of them it is acknowledged that the relative incidence of the endotheliomata varies according to the point of view of different pathologists. In some laboratories the diagnosis of an endothelioma is a commonplace of routine work; in others it is rarely and unwillingly indulged in. This state of affairs is obviously *unsatisfactory* and reflects both upon our skill and upon the scientific standards on which our work is supposed to be based. In point of fact, when the subject is considered critically, it appears that the diagnosis of the endotheliomata rests on a very precarious basis, and *there* is no doubt *that* it is a common practice to label a tumour an endothelioma because, as it is said, it is impossible to force it *without violence* into any of the accepted groups of carcinomata and sarcomata. Inasmuch as this attitude of mind presupposes a finite knowledge of the histological potentialities of the malignant epithelial and connective tissue cell, it cannot be considered scientifically correct; and it is certain that in the past it has led to grave errors. When, for example, the sarcomatous transformation of the stroma of a carcinoma of the mouse was first observed, the opinion was freely expressed *that the* phenomenon could be explained on the assumption that the primary growth was really an endothelioma, and that the *sarcomatous tissue* represented another phase of the growth of the endothelial cell. This, of course, we now know to be untrue.

In Adami's classification the endotheliomata are grouped under the transitional lepidomata, and he teaches that in conditions of new growth they may assume either carcinomatous or sarcomatous characters. This is a *convenient* doctrine, but one which, in our experience, is not borne out in practice. On the other hand, we hold that the power of polymorphic growth possessed by the malignant epithelial cell has been insufficiently recognised. The carcinoma cell does not always *conform* to type, but may vary so greatly from the elements of the general run of tumours derived from similar epithelium as to be scarcely recognisable.[1] We would describe many so-called endotheliomata as atypical carcinomata, including the large group occurring in the parotid and other salivary glands.

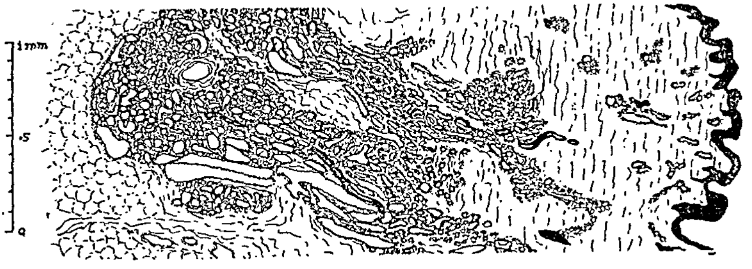
Another diagnostic feature of these tumours has been the supposed relation of their cells to *blood* or lymph vessels, and endotheliomata and peritheliomata have been described in the belief that the neoplastic cells grow either into, or away from, the lumen of the vessel from which they arise. It is difficult to see, however, how such a relationship can persist. In the ordinary course of events the normal structure of the tissues must be totally obscured by proliferation of the tumour cells, and in growths of any but microscopic size the site of origin must be indistinguishable. The only possible explanations of such appearances are either permeation within the lumen of a vessel or in the lymphatics surrounding it, or the survival of tumour cells which are more favourably situated than their fellows in respect to the vascular supply of the part.

FIG. 1.



Cutaneous hæmangeioma. Low-power drawing. The tumour is of the capillary type.

FIG. 2.



Low-power drawing of hæmangeioma of skin. The capillary structure is maintained but there is moderate proliferation of the endothelium.

Behaviour of the Neoplastic Endothelial Cell.

These criteria, then, have little to recommend them, and it is plain that if we are to arrive at any more definite conceptions as to what constitutes an endothelioma we must approach *the* problem in another way. The logical, and indeed the obvious, way is to determine, if possible, how the neoplastic endothelial cell behaves, and what *forms it can assume; that is,* to establish definite standards and to insist that any tumour shall conform to them before it can be called an endothelioma.

Some three years ago one of us[2] described two interesting vascular tumours which were remarkable in the close resemblance *their* cells bore to vaso-formative tissue, and the way in which they developed into capillary vessels or arranged themselves as lining membranes. It seemed worth while to determine whether these properties were shared by the *cells of* vascular tumours as a whole, and to this end we have collected and examined in detail a large number of such growths. And since our object was to endeavour to establish standards for the recognition of the neoplastic endothelial cell, we have worked chiefly with angeiomata so that our material might be free from the criticism that the tumours were not really of endothelial origin.

The majority of our tumours are cutaneous or subcutaneous angeiomata, which are admirable material *for an* investigation of this kind since they are more or less innocent and closely resemble normal vascular tissue. They form a series running *from the simple* capillary angeioma to the more solid or compact hæmangeioma simplex. The simplest types consist of collections of dilated capillary vessels filled with

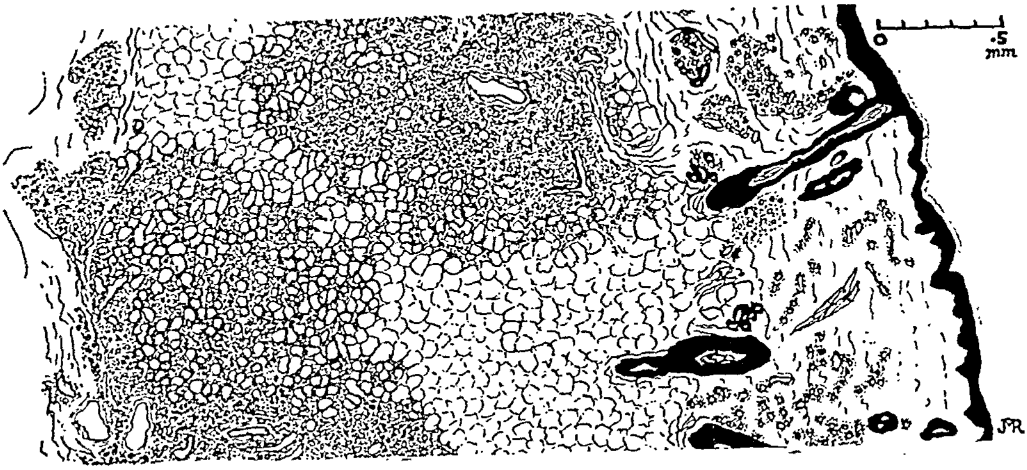
FIG. 3.

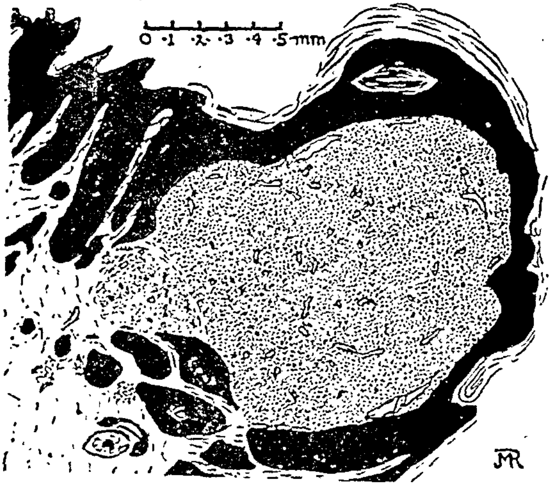


Low-power drawing of hæmangeioma of skin. The structure is more compact though capillaries are still well formed, especially beneath the epidermis. Infiltrative growth is well shown.

circulating blood. (Fig. 1.) In the more complex variety the angeiomatous structure is still maintained but the capillaries are lined by a double or triple layer of cells and the spaces between the closely set vessels are occupied by endothelial cells. (Figs. 2 and 3.) In the most atypical or compact form the tumour consists of a dense felted mass of endothelial cells and contains but few rudimentary capillaries. (Fig. 4.) It is not possible, however, to adopt any hard-and-fast classification along these lines, for intermediate forms, in which the capillary and the compact structure are both present, occur quite frequently, and there is an important group, an example of which was described in the article to which we have already referred, in which complex systems of simple capillaries are associated with areas of atypical solid growth. Most of these growths are comparatively innocent; only in the more compact forms do the numerous mitoses and the absence of well-developed capillaries suggest malignancy. But practically all of them have remarkable powers of infiltration; they are never encapsuled; their margins are ill-defined, and they extend widely throughout the subcutaneous tissues, or, should they be situated more deeply, among the individual fibres of muscle bundles. This, of course, is well recognised, and it is also generally agreed that the tumours increase in size from their own resources. In a few instances we believe that we have been able to trace connexions between the tumour capillaries and the normal vessels of the part, and it is possible, therefore, that there may be multiple foci of origin continuously developing. The evidence for this, however, is very meagre, and there is no doubt that usually increase in size is due to the actual proliferation of the tumour cells.

According to the generally accepted teaching, the growth of the hæmangeiomata takes place by a process of budding from the cells lining the capillaries. These buds grow out as long processes into the connective tissue, and eventually channels are formed by the approximation of adjacent processes or the splitting of parallel rows of cells. Fraser[3] states that "active proliferation of the endothelial cells is always occurring, and it is possible to demonstrate the development of fresh formation of vessels. Within the accumulation of several endothelial cells, which have proliferated from the walls of an existing vessel, a vacuole makes its appearance, and by its enlargement establishes the lumen of the future vessel. Around the central vacuole the endothelial cells become so arranged as to form the vessel wall." Our own observations suggest that the process is rather more complicated. The tumour cells are usually ill-defined. They possess a scanty reticulated cytoplasm and comparatively large oval or spheroidal nuclei, with a fine chromatin network. In the younger cells the cytoplasm is more dense and the cell outlines can be distinguished with ease, but in the older cells the cytoplasm becomes fibrillar or reticular, and it is scarcely possible to separate the individuals in the closely-packed masses of cells. There is one characteristic feature, however, which is constantly seen; that is, the development of small intracellular vacuoles, which gradually increase in size and flow together till eventually the greater part of the cell is occupied by a single vacuole around which the nucleus and the remains of the cytoplasm are folded and compressed. The next step is the rupture of the walls of adjacent cells, so that neighbouring vacuoles become thrown into one, and in this way irregular spaces are developed which in time come to contain blood. Though in many tumours these spaces remain more or less irregular in shape, in others the lining cells become arranged as a definite endothelium and practically normal capillaries are produced.

FIG. 4.



Low-power drawing of hæmangeioma of the skin. The tumour is solid and shows practically no capillary differentiation.

This, then, is the mode of growth of this particular group of tumours, and it recalls very closely the method of formation of vascular tissue from the primitive vaso-formative cells of the embryo. The cells of the tumour capillaries proliferate and extend as buds or processes into the neighbouring connective tissue. In

---

[3] Fraser, John (1920): The Hæmangeioma Group of Endothelio-Blastomata, British Journal of Surgery, vol. vii., p. 335.

course of time they become vacuolated and the vacuoles of adjacent cells coalesce and establish communication with the parent capillary, and the nuclei with the *remnants of the cytoplasm form an endothelium to the* new-formed vessel. This process is illustrated in Figs. 5 to 7.

Fraser[4] states that these tumours spread by individual enthothelial cells which afterwards proliferate and become vacuolated, eventually forming the embryonic capillary tissue. But his description of the formation of capillaries in an earlier part of his article, which we have already quoted, suggests that the vacuoles arise by the grouping of neighbouring cells, not by development actually within the cell and it is this intracellular formation of vacuoles which we hold to be important. It is a common phenomenon in vascular endothelium under pathological conditions; it represents a fundamental property of the embryonic endothelial cell, and it is, we believe, the method of formation of lumina in endotheliomata of lymphatic as well as vascular origin. If we recognise that the lumina of endotheliomata are produced in a definite way, by an *attempt at functional activity by the neoplastic cell, it* should enable us to distinguish them from similar *formations in the carcinomata either from necrosis or* from incomplete development into glandular tissue.

FIG. 5.

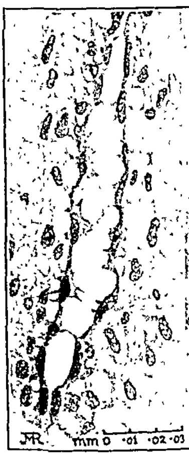
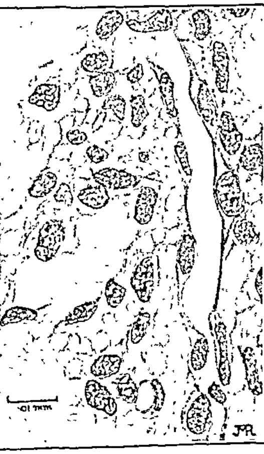
FIG. 6.



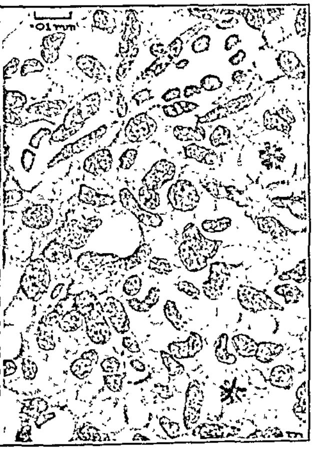
High-power drawing of another part of the tumour illustrated in Fig. 5, showing a further stage in the formation of a capillary from the tumour cells.

FIG. 7.



High-power drawing of a section from a subcutaneous angeioma showing a later stage in the formation of a capillary.

FIG. 8.



High-power drawing of section illustrated in Fig. 4. The tumour is growing *rapidly*, two *mitotic* figures are present in the field, and there is no true differentiation. Intracellular vacuoles are present, however, and irregular blood-containing *spaces are formed by their coalescence.*

More Complex Tumours.

So far we have been dealing with tumours which can all be grouped as angeiomata—that is to say, they all show a greater or less degree of differentiation and form recognisably vascular tissue. Our material also contains a considerable number of hæmendotheliomata, tumours in which, while it is still possible to recognise the type cell, differentiation is rudimentary or absent altogether. *It would serve no useful purpose to describe* any number of these tumours in detail; one or two examples are sufficient. But we would emphasise the fact that when a diagnosis of endothelioma is possible in these more atypical forms it is because of the tendency of the tumour elements to revert to the primitive vaso-formative type of cell. We do not believe that any reliance should be placed upon the relationship of the vessels of the stroma to the tumour parenchyma, or upon the intimate association of blood corpuscles with the tumour cells. These are not features upon which the diagnosis of an endothelioma can be based. Another observation on which we would lay stress is a negative one, but not, we think, the less important for that. *In our experience the neoplastic* endothelial cell may assume one of three forms: it revert to the primitive vaso-formative type of cell. may *lose all the characteristic* features of endoth and grow as a spindle cell, when it gives simple undifferentiated sarcoma; or it may *into* a flattened pavement type of cell, however, departing so far from the normal

---

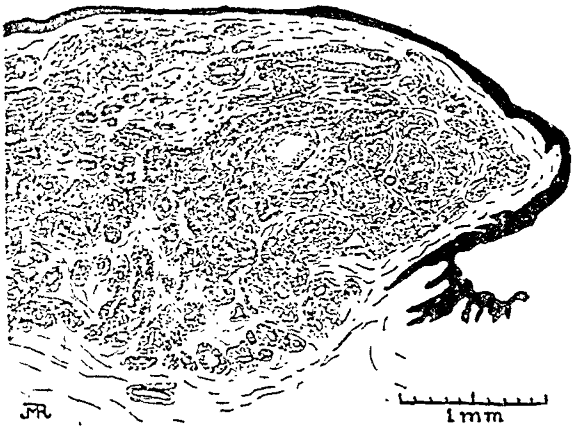
FIG. 9.



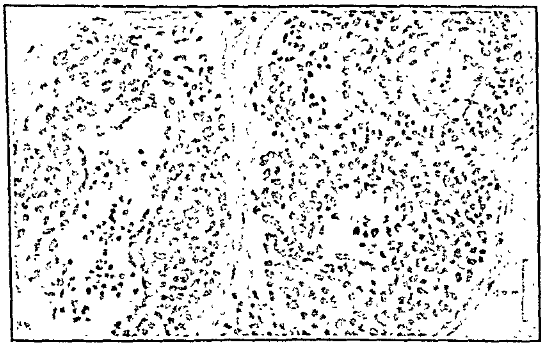
Low-power drawing of a hæmangeioma showing the alveolar type of growth.

unrecognisable. Within these limits it remains a comparatively simple element, and we have entirely failed to observe those extreme instances of polymorphism which are commonly held to be characteristic of endotheliomata.

Among the more common atypical endotheliomata is a group intermediate in structure between the hæmangeioma simplex and the pure sarcoma. One of these is illustrated in Fig. 8. Growth is rapid and mitotic figures are numerous, and though the tumours are not so densely cellular as the sarcomata they differ from the hæmangeiomata in that they do not form definite capillaries. Nevertheless, the fibrillar structure of the cells and the tendency they exhibit to the formation of vacuoles makes it possible to recognise them as endothelial in origin.

Another interesting variety is the alveolar type, in which the tumour cells do not grow diffusely but are arranged in alveoli, so that there is a sharp distinction between parenchyma and stroma, and the structure resembles that characteristic of the epithelial neoplasms.

FIG. 10.



High-power drawing of section illustrated in Fig. 9, showing the pseudo-peritheliomatous structure. The lumina do not represent the remains of blood vessels but are new formations due to the coalescence of intracellular vacuoles.

An example of this type is illustrated in Figs. 9 and 10. The tumour consists of alveoli or branching columns of cells, many of which present central lumina which contain blood. At first sight the structure would suggest a perithelioma, but Fig. 10 shows the true nature of the growth. The central lumina do not represent blood-vessels surrounded by tumour cells, but are actual new formations, and the stages in their development from intracellular vacuoles are shown very clearly.

Finally, we may refer to the type illustrated in Fig. 11. In this there is a tendency for the tumour cells to adopt a flattened squamous form, and though they exhibit cytoplasmic vacuoles their endothelial origin is chiefly revealed in the way they grow out on long processes which form the linings of irregular spaces.

Summary and Conclusions.

We have examined a large number of vascular tumours in the attempt to distinguish and define the characteristic features of the neoplastic endothelial cell and so place the diagnosis of the endotheliomata on a more secure basis. We have found that in tumours which can be recognised as of endothelial origin the cells invariably revert to the primitive vaso-formative type, and that this reversion is adequate to explain the structure and growth of these neoplasms. We suggest that the mere relation of tumour cells to blood-vessels or to circulating blood is not conclusive evidence of an endotheliomatous origin, and that there is no evidence that the cells of an endothelioma can so closely resemble those of a carcinoma as to give rise to confusion. It is possible that this polymorphism can occur, for under certain conditions endothelial cells, especially those of serous membranes, can assume a cubical or even columnar form, but it has not been observed in any of the endotheliomata which have been examined. On the other hand, the more atypical endotheliomata progress gradually to a type of growth which is indistinguishable from a spindle-celled sarcoma. But in these, as in the hypothetical carcinomatous forms, differentiation is entirely lost, so that it is no longer possible to distinguish their endothelial origin, and there is no justification for including them among the endotheliomata. This name should be kept for tumours which reveal in their structure definite evidence of having originated from endothelium.

THE RELATION OF THE LIVER TO THE DIFFERENCE VALUE OF THE BLOOD.

BY P. J. CAMMIDGE, M.D. LOND.,
J. A. CAIRNS FORSYTH, F.R.C.S. ENG.,
AND
H. A. H. HOWARD, B.SC. LOND.

IN a previous communication[1] we brought forward evidence to show that the relation between the difference value and the sugar content of the blood, estimated at hourly intervals before and after a test-meal taken fasting, furnishes evidence as to the functional efficiency of the pancreas, and that the increase in the difference value associated with disease of the pancreas is dependent upon a diminished control of the gland over the glycogenic ferment of the liver, owing probably to a lack of its internal secretion. At a later date it was stated in a paper read by one of us before the Medical Section of the Royal Society of Medicine[2] that disturbances in the functions of the liver also change the relation normally existing between the difference value and the sugar content of the blood, but that when the estimations are made at hourly intervals after a meal a difference-value curve of an entirely distinct character to that occurring in association with pancreatic insufficiency is found. In this paper we propose to consider the experimental evidence on which this conclusion is based, and to discuss its bearing upon the original problem of our research—namely, the origin and significance of the dextrinuria of pancreatic disease.

Unlike the difference value of the blood associated with disturbances of the functions of the pancreas, which is abnormally high in the fasting state (Fig. 1), the difference value in hepatic derangement is within the normal limit of 0·005 per cent. and is often zero in the early morning before any food has been taken. After breakfast it gradually rises and continues to increase for several hours independent of the fall in the blood sugar which usually occurs at, or about, the third hour after the meal, until a level which may be 10 or 12 times the highest normal limit of 0·010 per cent. is attained. (Fig. 2.) In some instances the rise in the difference value is rapid and reaches its maximum in four or five hours after the meal, in others it takes place more slowly and does not reach its highest point until after a lapse of seven or eight hours. In any case it bears no constant relation to the blood-sugar curve, in contrast to what is found in pancreatic disease, where the blood-sugar curve and difference-value curve move regularly in opposite directions.

In order to test the correctness of the hypothesis arrived at on clinical grounds that a difference-value curve of this description is associated with disturbances in the functions of the liver we proceeded to carry out a series of experiments upon animals and tried to produce the curve artificially by interfering with the functional efficiency of that organ. For this purpose we selected injections of hydrazine phosphate. It is well known that certain drugs, notably phosphorus, chloroform, brombenzol, and hydrazine, have a toxic action on the liver, causing changes similar to those met with in acute yellow atrophy. Of these hydrazine is peculiarly suited to the investigation of hepatic insufficiency, as it was shown by Wells[3] to have a selective action on the hepatic parenchyma, and histological examinations carried out by MacAdam[4] confirmed the limitation of the toxic effect of the drug to the liver. Borisow, who was the first to point out the toxic action of hydrazine salts upon the liver,[5] employed the sulphate, and most subsequent observers appear to have done the same, but as we were unable to obtain a supply we were obliged to use the only available compound, the phosphate. This was given subcutaneously in a neutralised 2·5 per cent. solution. According to MacAdam, the lethal dose of hydrazine sulphate for a dog varies between 0·07 and 0·10 g. per kilo of body weight. As preliminary experiments proved that 0·025 g. per kilo of hydrazine phosphate gave rise to a violent reaction, which persisted for several days, we subsequently gave only 0·0125 g. per kilo, a dose we found sufficient to produce distinct symptoms of hepatic disturbances in the shape of slight jaundice and diarrhœa, with disinclination for food, lasting for 24 to 48 hours.

We first investigated the effects of hydrazine phosphate injections upon the carbohydrate tolerance and difference value of the blood.

Two dogs were given repeated sublethal doses of 0·0125 g. per kilo, at weekly intervals, after the normal blood changes induced by a weighed quantity of dextrose in one case and of lævulose in the other had been ascertained. Two days after the third injection the same amount of lævulose, given under exactly similar conditions, was found to produce a decided increase in the sugar content of the blood (Fig. 3), with a slower return to the fasting level than before the injections had been commenced, but there was no marked change in the difference values. Examination of the urine of this dog showed that lævulose, 0·6 per cent., was present in the urine, and it continued to pass lævulose subsequently when on a diet of meat and dog-biscuit.

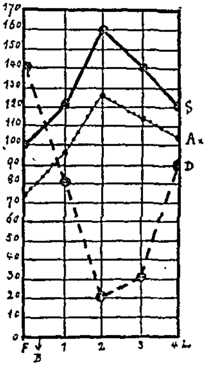

FIG. 1.—Chronic pancreatitis from invading gastric ulcer.

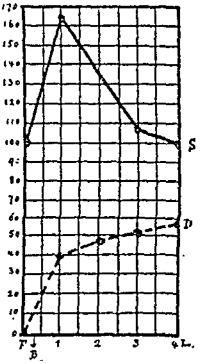

FIG. 2.—Hepatic insufficiency.

A, Amylolytic ferment × 10. F, Fasting. B, Breakfast. S, Blood sugar. D, Difference value.

In the other dog dextrose by the mouth two days after the third injection of hydrazine gave results practically identical with those obtained under normal conditions as regards the sugar content of the blood, but the difference value was decidedly higher than when a similar dose of the sugar had been taken before the injections, and it rose to about double the normal height at the end of two hours in a curve of the "hepatic" type.

Two more injections of hydrazine were given and the dose of dextrose was then repeated. Again the sugar content of the blood showed no striking deviation from the normal (Fig. 4), but the difference value rose from a fasting level of 0·004 per cent. to 0·018 per cent. at the end of two hours.

From these experiments it would appear that the injections of hydrazine lowered the animal's tolerance for lævulose but had no appreciable effect on its powers of dealing with dextrose. On the other hand, the sugar, which was poorly tolerated and appeared in the urine, caused no striking change in the difference value of the blood, whereas that which was retained as well after as before the injections gave rise to a difference-value curve of the "hepatic" type, which became more marked as the number of injections was increased. According to Strauss[6] and others, a diminished tolerance for lævulose is, with few exceptions, a characteristic sign of hepatic insufficiency, so that its occurrence after hydrazine injections lends further support to the conclusion that this drug has a toxic effect on the liver. This being the case, we may infer that the abnormal difference-value curve following the ingestion of dextrose is probably also an indication of hepatic insufficiency. The absence of a similar curve after lævulose had been taken is not easy to explain unless we assume that, as this sugar passes through the liver unchanged to a considerable extent, it does not induce the same metabolic changes as dextrose.

An experiment carried out by one of us upon himself suggests that dextrose may interfere with the normal metabolism of the liver under certain circumstances, and at the same time shows that the "hepatic" difference-value curve is a very delicate index of the functional condition of the liver. In our experience dextrose taken fasting by a healthy person does not increase the difference value of the blood, the only effect being a slight drop when the sugar content of the blood reaches its maximum level at the end of the first hour; when, however, the sugar is taken at the highest point of the blood-sugar curve following an ordinary mixed meal a rise similar to that found in a dog poisoned with hydrazine can be produced.

A test breakfast was taken by the experimenter, and at the time previous experience had shown the highest point of the blood-sugar curve to occur with a similar meal, 20 g. of pure dextrose, dissolved in water, were swallowed. The result was that the percentage of sugar in the blood continued to rise for another hour instead of falling as it otherwise would have done, and, what is the chief point, the difference value rapidly increased and continued to do so for at least an hour and a half, far above what had been found when no sugar had been taken. (Fig. 5.) Shortly after the sugar had been swallowed the experimenter felt nauseated and experienced uncomfortable sensations in the abdomen similar to those complained of sometimes by children who have indulged freely in sweets between meals.

As rabbits are better suited for repeated blood analyses than dogs most of our observations were carried out on them, but, since no data concerning the fatal dose of hydrazine phosphate were available, we had first to determine it experimentally.

For this purpose a rabbit weighing 1 kg. was given a dose of 0·025 g. of neutralised hydrazine phosphate subcutaneously after a sample of blood had been taken from the marginal vein fasting, and again one hour after a mixed meal of oats and green food. Twenty-four hours later the animal had apparently suffered in no way from the dose, but its blood showed a rise in the difference value from 0·006 per cent., the previous fasting level, to 0·010 per cent., and a fall in the sugar from 0·086 per cent. to 0·074 per cent.; there was considerable lipæmia, but no change in the amylolytic ferment. Another injection of 0·05 g. of hydrazine phosphate was then given. Next day the animal refused food and was seriously ill, passing liquid bile-stained motions. Examination of the blood now showed an enormous increase in the difference value, which stood at 0·100 per cent., a sugar content of 0·050 per cent., and an entire absence of amylolytic ferment. Two days later it was found dead. Post mortem the liver was seen to be enlarged and of a yellow colour. Microscopical examination showed vacuolation of the protoplasm with coarse granular changes, feebly stained nuclei, and small localised deposits of fat staining deeply with osmic acid. No other pathological changes were discovered.

It was evident, therefore, that hydrazine phosphate in the doses given produced in the liver of the rabbit profound degenerative changes affecting both the cell nuclei and the cytoplasm.

Having learnt from this experiment that the liver of the herbivorous rabbit is more resistant to the toxic action of hydrazine phosphate than the liver of the carnivorous dog, so that 0·025 g. per kilo is not sufficient to produce serious disturbances in its functions, while a further dose of 0·05 g. produces fatal results, we proceeded to inject a series of rabbits with a medium dose of 0·05 g. per kilo and studied the effects of different diets. In each instance specimens of blood were taken from the marginal vein for analysis before the meal and at hourly intervals after for five or six hours on the second and successive days following the injection. Earlier observations on the effect of food were not possible as the animals refused to eat for the first 48 hours.

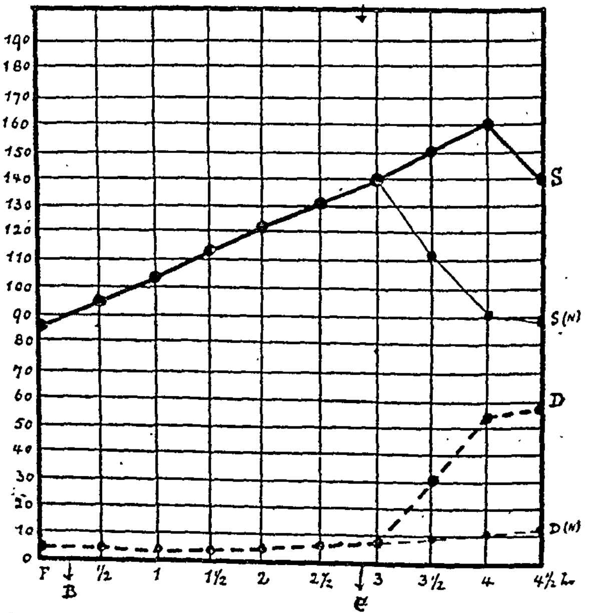

FIG. 5.—Dextrose after a meal in a healthy man. F, Fasting. B, Breakfast. G, Dextrose. S, Blood sugar. S (N), Blood sugar without dextrose. D, Difference value. D (N), Difference value without dextrose.

The first series of rabbits was fed on oats and cabbage. Two days after the injection the blood-sugar curve was found to follow a normal course for the first two hours after the test-meal (Fig. 6), but at the third hour the percentage of sugar was not as high as in a normal rabbit on similar food, and in the succeeding two hours it was still subnormal. By the fourth day after the injection this variation had disappeared and the sugar curve followed the same course as in a normal rabbit. (Fig. 7.) A much more striking change was found in the difference value. Forty-eight hours after the injection (Fig. 6) this stood at the normal level fasting, and showed only a very slight rise for two hours after the test-meal; it then increased rapidly, and at the fourth hour stood at ten times its previous height. After that there was a fall, which took place more slowly than the rise, so that at the sixth hour the fasting level had not been regained. The difference value four days after the injection

(Fig. 7) showed a similar rise, but it was slower in commencing, starting at the fourth hour instead of at the third, and failed to reach the same level at the maximum, five hours after the meal. On the seventh day (Fig. 8) the difference-value curve varied little from the normal, but still gave slightly higher figures at the fourth and fifth hours than in a healthy animal on the same food.

Another series of rabbits fed on thoroughly boiled (six hours) oatmeal porridge gave similar results, excepting that 48 hours after the injection the difference value commenced to rise an hour sooner and attained a maximum level 6 per cent. higher than had been found in animals fed on dry oats and cabbage. The delay in the rise in the difference value on the fourth and seventh days was likewise not so prolonged as in the other series, and on these days, too, the maximum height attained was about 10 per cent greater than in the corresponding rabbits of the first series.

In order that we might compare the blood changes in carnivorous and herbivorous animals we injected a dog weighing 10 kilos with 0·25 g. of neutralised hydrazine phosphate. For the first 48 hours it refused all food and was then with difficulty induced to eat an ounce of meat. As will be seen from the chart (Fig. 9) the blood-sugar curve, after a slight preliminary drop at the first hour, rose more slowly than in a normal dog after a similar meal and failed to attain the same maximum level. Although the difference-value curve was similar in its course to that met with in rabbits on a carbohydrate diet, the increase was not as marked and the maximum level attained was only about four times the normal.

On comparing the difference-value curves produced experimentally in animals with those found in patients exhibiting clinical signs and symptoms of disturbance of the functions of the liver it will be seen that they correspond very closely; it seems justifiable to assume, therefore, that the presence of a curve of this description is indicative of functional inefficiency of the liver, in the same way as the type of curve we described in our previous paper is a sign of functional inefficiency of the pancreas. The question then arises whether the substance, or substances, giving rise to the difference value of the blood is the same in hepatic as in pancreatic disturbances.

Analyses of the urine of patients exhibiting a typical "hepatic" curve in their blood after a meal, and of animals in which hepatic disturbances have been produced by injections of hydrazine, have shown that the difference value of the urine, estimated at hourly intervals, moves in a curve corresponding to the variations in the difference value of the blood, in the same way as the difference value of the blood and the iodine coefficient or difference value of the urine correspond in pancreatic disease. This suggests that in both conditions the increase in the reducing power of the blood and urine after boiling with dilute acid is dependent upon the presence of a hydrolysable carbohydrate, and, since the carbohydrate in the urine has the chemical properties and composition of a dextrin, it is probable that the hydrolysable carbohydrate in the blood is also of a dextrin-like nature. In spite of the similarity of the reacting substance it is unlikely that its origin is the same in the two conditions however, for while the difference value is highest in pancreatic affections when the patient is fasting, it is then normal, or subnormal, in hepatic disorders; further, the difference value varies inversely as the percentage of sugar in the blood in diseases of the pancreas, but in affections of the liver it rises irrespective of any increase or decrease in the sugar, to which it bears no constant relation. The fact that the excursion of the difference-value curve of the blood above the normal, on the same diet, after a sublethal dose of hydrazine diminishes with the lapse of time, and as the injury of the liver is repaired, shows that the substance giving rise to the difference value in hepatic derangement is either formed by the liver in response to the ingestion of food or is a product which is normally intercepted and stored by the liver cells. That the latter is the more probable explanation is suggested by the higher difference value found in rabbits fed on thoroughly boiled oatmeal than in those receiving uncooked oats and raw cabbage. Uncooked oatmeal contains no dextrine and about 0·8 per cent. of reducing sugar; when coarse oatmeal is boiled with water the percentage of sugar slowly increases, so that at the end of six hours it attains to about 6 per cent., meanwhile dextrins appear and reach a maximum of about 45 per cent. between the sixth and seventh

hours, after that the proportion of dextrin diminishes and the reducing sugar rapidly rises. Previous experiments[7] have proved that the mesenteric blood of rabbits fed on dextrinised (six-hour) oatmeal contains about 25 per cent. of dextrin compared with under 2 per cent. in oat-fed rabbits, but that the difference value of the peripheral blood in normal animals is the same on both diets. Since, therefore, the effect of hydrazine injections is to raise the difference value more when the mesenteric blood contains a higher proportion of dextrin it seems reasonable to infer that it is due to a diminished ability of the liver to retain dextrins coming to it from the intestine, and that they consequently leak into the peripheral blood. The slow and steady rise in the difference value, commencing more rapidly after a meal of dextrinised carbohydrate than after uncooked starch, and its persistence for several hours would be consistent with a gradual absorption from the alimentary tract, while the comparatively slight increase produced by a meat meal in the dog tends also to support this conclusion. Such an explanation would further account for the very delayed rise in the difference value sometimes met with in patients suffering from digestive disturbances, but not encountered in animals with presumably healthy digestive tracts.

Before coming to the conclusion definitely that the rise in the difference value of the blood following a meal in hepatic derangements is entirely and invariably due to the passage into the peripheral circulation of dextrins derived from the food, we must consider the effects following the injection of hydrazine in fasting animals. Small doses produce no characteristic change, but when larger injections are given the difference value of the blood rises, and shortly before death from a lethal dose it reaches a level far in excess of that encountered in any animal which has received only a sublethal dose, no matter what the nature of the diet. In spite of the high difference value of the blood the urine of such an animal gives a normal difference value and iodine coefficient, showing that in this case the hydrolysable carbohydrate of the blood does not pass through the kidneys. As the increase in the difference value occurs in a fasting animal, the substance giving rise to it cannot have come direct from the food. In a previous paper we showed that the substance giving rise to the high difference value in the fasting condition in pancreatic affections is probably derived from glycogen stored in the liver, and it seems likely that the increase in the difference value of the blood in a fasting animal the subject of a destructive lesion of the liver may have a similar source; but as the hydrolysable carbohydrate met with in pancreatic affections is dialysable and passes into the urine, whereas after a lethal dose of hydrazine it is non-dialysable and does not appear in the urine, it is evident that the circulating carbohydrate is not the same. The key to the different physical properties of the abnormal hydrolysable carbohydrates of the blood in the two conditions possibly lies in the absence of amylolytic ferment in the animals poisoned with hydrazine and its presence in excess in pancreatic lesions. In our experiments upon depancreatised dogs we found that the amylolytic ferment of the blood increased as the functional activity of the pancreas was interfered with by the excision of larger proportions of the gland, but that even when the whole organ had been removed the usual increase and decrease following a meal took place. From this we inferred that the ferment is not derived from the pancreas, but originates in some other tissue, which is under the control of the pancreas, however, probably through its internal secretion. The balance of evidence suggested that the liver is the most likely source of at least the bulk of the amylolytic ferment of the blood, and observations made in the course of these experiments tend to confirm this conclusion. In a fasting animal small doses of hydrazine produce no appreciable alteration in the ferment content of the blood, but as the amount of hydrazine injected is increased and more profound degenerative changes are produced in the liver the percentage of ferment steadily drops, so that eventually it disappears entirely some 24 hours before the animal succumbs to a fatal dose. If, then, as our previous experiments have suggested, the breaking down of stored glycogen in the liver is effected through the agency of an amylolytic ferment which passes into the circulation along with the products of its activity, the absence of such a ferment will probably be associated with a more or less complete failure of the usual hydrolytic processes, so that any glycogen set free by destructive changes in the hepatic parenchyma will appear in the blood as such, or in the form of some closely related non-dialysable compound, consequently the difference value of the blood will be raised but the iodine coefficient of the urine will be unaffected. When, on the other hand, the ferment is produced in increased amount it will break down glycogen through the usual dextrin stages to maltose and glucose, but more quickly and completely than normal; if the pancreas is still capable of exercising the controlling influence we have previously suggested it possesses, however, it may not be able to prevent the initial stages of the degradation of glycogen arising from the increased activity of the liver ferment, but it may interfere with their progress and cut them short to a considerable extent at the dextrin stage, so that dialysable substances of this nature pass into the circulation and, being excreted in the urine, raise the iodine coefficient in proportion to the increase in the difference value of the blood. If we apply a similar process of reasoning to the blood conditions produced by a meal in an animal which has previously received a sublethal dose of hydrazine it would appear likely that the rise in the difference value may be partly explained by changes in the liver similar to those following a lethal dose in a fasting animal, for on the second day after the injection the amylolytic ferment did not show the normal rise and fall corresponding to the sugar curve subsequent to the meal which had been met with in a normal animal on the same food; by the fourth day it rose a little, but more slowly and still not to the same maximum level as in health, but on the seventh day, when the animal had apparently recovered almost entirely from the effects of the drug, it followed a normal curve. Assuming, then, that a defective formation of amylolytic ferment is associated with retarded glycogen hydrolysis, the rise in the difference value, and especially that occurring two days after the injection and within three hours after the meal, might be due to dextrins derived from the liver store. That the rise in the earlier hours after the meal particularly is partly attributable to this cause is also suggested by the subnormal blood sugar, since, as we have already seen, one of the effects of a lethal dose of hydrazine is to depress the sugar content of the blood.

Summary.

(1) The difference value of the blood, estimated at hourly intervals before and after a test-meal, follows an abnormal course in conditions where the functions of the liver are interfered with.

(2) This "hepatic" curve differs markedly from the type of curve associated with pancreatic affections previously described, and bears no constant relation to the sugar content of the blood.

(3) The increase in the difference value of the blood following a meal in disease of the liver is chiefly due to hydrolysable carbohydrate, probably of a dextrin-like nature, absorbed from the alimentary tract, which is permitted to pass through the liver into the peripheral circulation instead of being retained as it is normally.

(4) Dextrin-like bodies derived from the glycogen store of the liver may be a contributory factor in the production of the raised difference value under certain circumstances.

(5) Destructive changes in the hepatic parenchyma are associated with a diminution of the amylolytic ferment content of the blood, thus tending to confirm the conclusion that the liver is the main source of that ferment.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

A CONDITION SUGGESTING LUPUS PERNIO IN A CHILD.[1]

BY F. PARKES WEBER, M.A., M.D., F.R.C.P. LOND.

THE patient, a boy aged 2½ years, shows a remarkable condition of his face, hands, and feet. This condition, in regard to the hands and feet, might almost be termed "acrodermatitis chronica mutilans."

There is extreme redness, sometimes associated with lividity, of the cheeks and chin. On the cheeks there are also fine hair-like superficial telangiectases. The skin of the cheeks is slightly scaly, and feels slightly thickened and infiltrated when one pinches it up. The edges of the pinnæ of the ears are very hyperæmic and also scaly, as in the subjects of so-called "chilblainy circulation" during winter. There is ozæna, with an offensive muco-purulent discharge from the nose, the bridge of which is very depressed. The arms and legs show red, sometimes livid, reticular mottling. The hands present a very mutilated appearance, especially the right hand, the tips of some of the fingers having been lost by gangrene or ulceration. The skin of the hands has sometimes been swollen and red or cyanotic, but lately has become less turgid and paler. None of the toes have been lost, but the feet have been swollen and red or livid, like the hands; in the sole of each foot there is an irregularly shaped, chronic ulcer. Of late the feet have been less swollen and paler, and the ulcers have become smaller.

Otherwise the child's condition does not appear bad. Mental development seems to be normal. There is occasional moderate fever, probably connected chiefly with the nasal disease. There is no evidence of disease in the thoracic or abdominal viscera, excepting that a Rontgen skiagram of the thorax (Dr. James Metcalfe, March, 1921) shows a chain of enlarged hilus glands on the right and some hilus thickening on the left side; also slight shadowing in the mediastinal area. There is no enlargement of the superficial lymphatic glands nor of the liver or spleen. The urine is free from albumin and sugar. Blood count (March, 1921): erythrocytes 4,300,000, and white cells 6100, to the cubic millimetre of blood; hæmoglobin 90 per cent. The differential count of white cells gave: lymphocytes, 38·3 per cent.; polymorphonuclear leucocytes, 61·7 per cent.; no eosinophiles or mast cells were seen during the count. There was no poikilocytosis or polychromatophilia, and no abnormal cells of any kind were found. Rontgen skiagrams of the hands show, besides more or less complete loss of some of the phalanges (owing to the tips of some of the fingers having been destroyed), small areas of imperfect calcification or of decalcification (such, as Dr. H. G. Adamson kindly tells me, have been noted in cases of lupus pernio). A microscopical ("biopsy") examination of a small piece removed (Feb. 28th, 1921) from the edge of the chronic ulcer on one foot showed the corium permeated with lymphocytes, plasma cells, and fibroblasts; no giant cells and no tubercle bacilli discovered.

The patient's parents are apparently quite healthy, and their other child is a bright, well-built, normal-looking boy, aged 8¼ years. The mother has had no other children and no miscarriages. The blood serum of both the patient and his mother gave a negative Wassermann reaction on two occasions. This was when the patient was under Dr. E. A. Cockayne's care, previously to Oct. 22nd, 1920, when he first came under my care. Dr. Cockayne also kindly informs me that an acid-fast bacillus was discovered in the nasal discharge. For the early history of the case I must refer to Dr. Cockayne's account.[2] When Dr. Cockayne showed the case (January, 1920) I agreed with him that it was one of a kind of sclerodactylia. Afterwards, in spite of the patient's early age, I thought that it was allied to lupus erythematosus, and Dr. Adamson suggested that it more nearly resembled lupus pernio. The symptoms in the left hand apparently commenced at 3 weeks of age. The offensive nasal discharge was first noticed at the age of 10 weeks, and has continued on and off since then. The child was breast-fed for the first seven weeks of life, and then brought up on various milk foods. There seems lately to have been a slight improvement under arsenical treatment. A thorough trial of mercurial treatment was made by Dr. Cockayne, but with no obvious benefit. Benzyl-benzoate, pituitary gland substance (by the mouth), and adrenalin (subcutaneous injections) have also been given, but without any striking good result. The child's weight on Oct. 25th, 1920, was 1 st. 3 lb. 1 oz.; and on March 14th, 1921, it was 1 st. 5 lb. 11 oz.

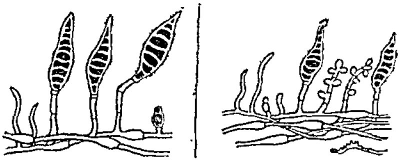
Dr. J. H. Sequeira has suggested that the case may be an exaggerated example of the toxic condition in very young children, described as "erythrœdema," by *Dr. H. Swift and Dr. A. J. Wood*, and previously spoken of by Dr. W. Snowball (Melbourne, Australia) as "raw-beef hands and feet."[3]

A NEW VARIETY OF RINGWORM.

BY ROBERT CRAIK, M.D. GLASG.

A HEALTHY girl, aged 21, had in October, 1916, a skin eruption on her thigh. It began a fortnight before as a small red point which was thought to be a bite, and was now about the size of a shilling and quite suggestive of ringworm. Fine scales showed plenty of mycelium. The source of infection remained unknown. Treatment was soon successful.

Seeded on wort agar fine particles gave good growths. At first grey and semi-transparent, after the sixth day, at room temperature, a white floury centre appeared and spread over most of the culture. In plate cultures this centre, under a low power, was a forest of upstanding, large, rough, multiseptate spindles; and the peripheral zone showed matted mycelium with a smooth surface on which were a few scattered small spindles and a few simple, attenuated, sterile, aerial hyphæ. Under a higher power (1/6 in.) a slide preparation showed pyriform swelling at the septa in several hyphæ; many large spindles were seen to have 6–9 septa and thick walls conspicuously rough on the outside. Repeated culture on several media at various temperatures gave no material change except in rate of growth.



The figure shows *M. audouini* var. *canis* on the right and the new variety on the left.

1. The pyriform swellings at the septa, even in young cultures, are characteristic of microsporon.

2. The floury centre contrasts with the downy centre of *M. audouini*. Microscopically total absence of acladium conidiophores explains this, for these are abundant on all media in microsporon of the child, and form the white down on its cultures. The multitudes of coarse spindles forming the floury centre are not present in microsporon of the child, which is remarkable for scarcity of little divided spindles.

3. In microsporon of the dog large spindles are fairly numerous, but its cultures also bear numerous acladium conidiophores—one is as important as the other. Under stress of circumstance the new organism has completely scrapped the primitive acladium conidiophore and staked its existence on multilocular spindles, which it produces in countless numbers.

The microsporons are usually regarded as one species, *M. audouini*, with two varieties—*M. audouini* var. *canis* and var. *equinum*. Obviously var. *canis* is only halfway between *M. audouini* and the new variety which deserves the name var. *macrosporium*. This plurality of conidial forms in microsporon, these elaborate multilocular spindles and the constantly hall-marked mycelium, are reminiscent of certain higher ascomycetes. Under pathogenic conditions such forms are never seen. It is to be inferred that such an organism, growing well on ordinary media at ordinary temperatures and passing through a parasitic phase in which development is much restricted, leads a double life in nature for which the conidial forms are designed.

Ealing, W.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF OBSTETRICS AND GYNÆCOLOGY.

EXHIBITION OF CASES AND SPECIMENS.

A MEETING of this section of the Royal Society of Medicine was held on May 5th, Professor HENRY BRIGGS, the President, being in the chair.

Mr. HENRY CURTIS communicated a case of

Angioma of the Vagina Spontaneously Evacuated.

The patient was a single woman with intact septate hymen. Two years before being seen by Mr. Curtis the patient, then aged 32, for the first time became aware of a protrusion from the vagina, which remained for a month and then gradually receded. Six months after it had completely disappeared, but reappeared five months later, and thenceforward regularly a few days before each period. Its appearance was associated with aching pains across the back at the bottom of the spine. The protrusion was described as appearing in the form of two or three lobes, usually of a bright red colour, but rarely dark red. On two or three occasions it projected for half an inch or more, but receded when the patient lay down, and it disappeared with the period. On examination a narrow hymeneal orifice, obstructed and reduced in size by an obliquely placed bar-like septum was found. The urethral orifice was normal, and showed no trace of a caruncle. Nothing abnormal could be detected within the vagina or external to the hymen. A few months after her first visit the patient stated that at the end of a period, after some offensive discharge, a fleshy mass had been spontaneously expelled from the vagina. On examination no trace of a pedicle or of any nævoid structure could be detected. Mr. Curtis suggested that the septate condition of the hymen had strangulated the growth and helped to cut through the pedicle. Six months later there had been no local recurrence. The fleshy mass expelled was of a pinkish-red colour, resembling a blood-clot. The specimen, when imbedded in paraffin, measured 2·7 cm. by 0·9 cm.

Mr. Curtis considered that the growth could not have arisen from a caruncle, and that though its surface had been denuded of epithelium its origin from the vagina rather than from the cervix or body of the uterus was indicated by the absence of any glandular tissue and characteristic stroma. Dr. E. H. Shaw had made a report on the microscopic appearance of the tumour, in which he stated that it was most probably a nævus, and gave his reasons for suggesting that a nævoid hypertrophy of one of the rugæ of the vagina was the most likely origin.

Dr. H. RUSSELL ANDREWS showed a specimen of

Carcinoma of the Uterus originating in an Adenomyoma.

The patient, a single woman aged 52, was sent to him in November, 1920. The menstrual periods had stopped completely three years previously after almost continuous bleeding for a year. In July, 1920, there was slight bleeding, and in September four weeks' bleeding ending with a flooding, but no hæmorrhage during the last month. She was well-nourished and had not lost flesh; for five or six months she had felt tired and had had some pain in the right iliac fossa. Lately there had been "neuralgic pain" in the lower abdomen. Nothing abnormal was found on abdominal examination. On bimanual examination the cervix was found to be normal; the body of the uterus was considerably enlarged. Under an anæsthetic the body of the uterus was found to be as large as a three months pregnancy. Dr. Andrews thought that the condition was probably carcinoma of the body of the uterus with fibroids and proceeded to perform hysterectomy. The operation was difficult, as the rectum was adherent to the back of the uterus and the parametrium was dense and inelastic, making dissection difficult. The pelvic peritoneum was studied with minute nodules resembling miliary tubercles. Both tubes were considerably enlarged and contained caseous material. The patient made a good recovery and was in good health five months after the operation.

Naked-eye description of the uterus and tubes.—The uterus measures 12 × 9·5 × 9 cm. The peritoneum is covered with coarse, fibrous tags and has scattered over it raised, solid, pink nodules of various sizes, most of them very small. The wall is soft, except in the fundus and the right cornu where there are two rounded nodules, which on section show a pink and white whorled surface and a few small cystic spaces. The endometrium is smooth and thin. The cavity of the uterus is irregular and enlarged. Both tubes are thickened and contain white or grey caseous material.

Microscopical appearances.—The endometrium is atrophic and shows no malignant change. Sections taken from various parts of the uterine wall show carcinomatous change in an adenomyoma. A few small areas of unchanged adenomyoma can be found. The nodules seen in the peritoneum consist of tubular or solid columnar-celled carcinoma. Both Fallopian tubes are filled with the same growth.

Dr. Andrews said that cases of adenomyoma becoming carcinomatous with no carcinomatous change to be found in the endometrium were very rare. On the suggestion of Dr. HERBERT SPENCER the specimen was referred to the Pathological Committee.

Dr. ARTHUR E. GILES opened a discussion on

THE PROGNOSIS AND TREATMENT OF STERILITY.

He said that he proposed to touch on two of the general aspects of the subject, the prevalence of sterility and the responsibility of the male partner, and then to sketch out three types of sterility in women, viewed from the standpoint of prognosis and treatment: Inevitable and incurable sterility, functional sterility, and conditions that cause or favour sterility but allow of treatment. Data and statistics referred to were derived from his recent monograph.[1]

The Prevalence of Sterility.

Estimates of the proportion of infertile marriages varied with different authors and in different countries between 2 and 20 per cent.

Dr. Giles's own case papers showed that among 3128 married women who were seen *as patients* the percentage of sterile cases was 22·2. Many of these were still young; when he took into consideration only women who had reached the age of 40 the percentage dropped to 15·3. In a large proportion of cases the women sought advice on account of some disease of the reproductive organs; and it was therefore certain that among an equal number drawn from the community at large the proportion of sterile women would be notably less. In Dr. Giles's opinion the proportion of sterile marriages in this country was well below 15 per cent. Difficulties in comparing statistics given by various writers arose because still-births were taken into account by some but not by others, while miscarriages and extra-uterine pregnancies were mostly overlooked or ignored. A woman who has conceived should not be regarded as sterile, even though the ultimate product of conception were not a living child. Dr. Giles was disposed to regard as being nearest to the truth the estimate of Simpson, who found the proportion of unfruitful marriages to be 10·9 per cent. in village communities and 16·3 per cent. in families of the aristocracy. The ratio was probably higher in towns than in the country. In any case the proportion was undesirably and unnecessarily high, the actual figures being of only academic interest. The only way to obtain a really reliable estimate of the number of unproductive marriages would be to get the particulars of at least 1000 marriages in which the wife was under 35 and the husband under 40 at the time of marriage and married life had lasted at least 15 years. But even these figures would not tell us the proportion of sterile *women* in the community, because in a number of cases the husband would be at fault.

The Responsibility of the Male Partner.

Estimates varied widely as to the proportion of cases in which the husband is to blame. Court placed it at 10 per cent., Duncan at 12 per cent., Brothers at 20 per cent. (based on 250 cases), Engelmann at 25 per cent., Hühner at 41 per cent. (186 cases), and Noeggerath at 90 per cent.

Noeggerath was apparently obsessed by the idea that gonorrhœa was the one important factor in the causation of sterility, and both he and Engelmann include under man's responsibility all cases of disease in the female which are directly traceable to the male. Dr. Giles pointed out that while it was no doubt morally justifiable to blame the man who had made his wife sterile by giving her gonorrhœa, from the statistical point of view this led to fallacious results; for while the woman whose tubes have been destroyed by gonorrhœa is permanently sterile, the man who infected her may remain quite capable of procreating children. But the actual figures were less important than the recognition of the principle that in doubtful cases the responsibility of the wife should not be assumed, and that she should not be submitted to operative procedures before definite evidence that the husband is healthy has been obtained.

---

[1] Sterility in Women. By Arthur E. Giles, M.D., &c. London: Henry Frowde, Hodder and Stoughton, Oxford University Press. 19.9.

Inevitable and Incurable Sterility in Women.

Cases of incurable sterility were easier to recognise if the conditions necessary for successful impregnation were borne in mind. These were, on the man's part, ability to deposit healthy seminal fluid in contact with the os externum cervicis; on the woman's part, (1) ability to receive this fluid in contact with the cervix; (2) such a healthy condition of uterus, tubes, and ovaries as would enable the spermatozoa to travel up to meet the ovum; (3) the production and discharge of healthy ova; and (4) such a healthy condition of the uterus as would enable it to harbour the fertilised ovum. Considering only the woman's side of the question, Dr. Giles said that under the first heading the conditions that caused sterility were absence of the vagina and want of communication between the vagina and the uterus.

Dr. Giles quoted cases in which the patient had stated that intercourse was normal and on examination it was found that the vagina ended blindly in a cul-de-sac. In such a case the woman had never menstruated. Sometimes the lower end of the vagina was patent, and to tell whether there was merely a septum across an otherwise developed vagina, or whether the upper part of the vagina was absent, a dissection of the parts might be necessary. The construction of an artificial vagina in the absence of a natural one Dr. Giles considered a hopeless procedure from the point of view of sterility and an unnecessary one from any point of view. The second condition for impregnation was unfulfilled in the absence or marked under-development of the uterus in congenital atresia of the tubes and in occlusion of the tubal channel by inflammation. Pyosalpinx, which was due to gonorrhœa in about 95 per cent. of cases and to tuberculosis or *B. coli* infection in the remaining 5 per cent., certainly caused incurable sterility. Whether a tube that had become occluded by mild salpingitis could be made functionable by surgical means was doubtful. The third condition for conception, the production by the ovary of healthy ova, was very difficult to estimate. Since age and the action of X rays lead to ovarian atrophy we might presume that when this atrophy has come about ovulation ceases. But there are other conditions that apparently interfere with normal ovulation; for example, anæmia, chronic drug taking, certain febrile and some nerve conditions, including pituitary disease. Obesity might come into this category; certainly obesity and sterility were related; but whether as cause and effect, or whether both were the results of some disturbed metabolic process, we did not know. Nor did we know what factors disturbed normal ovulation, nor what was the influence, if any, of internal secretions thereon. If any product of internal secretion did play a part, the ovarian secretion was probably a product of ovulation rather than a causal factor in the process. The fourth condition was not strictly one upon which successful impregnation depends, since failure therein led to miscarriage, not to sterility. But patients were concerned less with the possibilities of conception than with the chances of having a living child. From this point of view cases of uterine tuberculosis, carcinoma and sarcoma of the body of the uterus, and uterine fibrosis must be regarded as hopeless and incurable. In the last-named condition the absence of the mucosa rendered impossible what has been described as the "nidation of the ovum."

Functional Sterility.

When a childless woman who had been married for some years gave a history of regular menstruation without undue loss or unusual pain, and on examination the pelvic organs appeared to be normal, the case might be regarded as one of functional sterility. There were then several possibilities to be considered. In the first place, complete intercourse might not for various reasons have taken place; secondly, the husband might be suffering from azoöspermia or from a deficient vitality of spermatozoa; and thirdly, it might be an instance of "sexual incompatibility." There existed cases where a husband and wife had been unable to effect a conception together and yet each had been fertile with a different mate.

Conditions that Cause or Favour Sterility but Allow of Treatment.

Considering the conditions that prevent normal intercourse Dr. Giles said that atresia of the vaginal orifice was a curable condition; but the prognosis as regards sterility depended on the stage at which treatment was undertaken. If the products of menstruation had been accumulating in the closed vagina for some time secondary changes inimical to conception might be set up in the mucosa of the uterus, and later in the tubes. But if the patency of the vagina was established early there was a good prospect of fertility.

In stenosis of the vagina and rigidity of the hymen dilatation of the vaginal orifice under anæsthesia by means of the fingers or with graduated specula is often sufficient, while in more pronounced cases of stenosis the vaginal wall should be incised vertically, and the resulting wound sewn up transversely. The prognosis was very good. In treating dyspareunia and vaginismus the source of pain during intercourse should be sought; it was most frequently in the neighbourhood of the vaginal orifice and the remedy was usually simple. More deeply seated pain might be due to a prolapsed ovary or some inflammatory condition of the appendages and abdominal operation might be needed. Inflammatory disease would, of course, require treatment on its own account, apart from the question of sterility; but a prolapsed ovary could be sutured up, and if associated with retroversion, the fixing of the uterus in place was often sufficient to lift the ovary out of the painful zone. Vaginismus was more difficult to treat; but a good dilatation of the vaginal orifice under anæsthesia would often help matters. This was a condition in which suggestion might play a useful part. Once the mechanical difficulty was overcome the prognosis as regards sterility was good, as long as the patient had not waited until she was handicapped by the factor of age. Tumours encroaching on the vagina, such as an ovarian tumour or a uterine fibroid situated in the pelvis, might cause a mechanical obstacle to intercourse. The treatment was, of course, surgical, and the prognosis depended on the possibility of leaving at least one ovary and a not too much damaged uterus. Dr. Giles gave details of a case in which a patient became pregnant three months after a myomectomy and hysteropexy, and had a normal confinement. Prolapse and procidentia were usually the sequel of child-bearing, and thus caused secondary rather than primary sterility. Dr. Giles preferred operative to pessary treatment, and had many records of pregnancy and normal confinement following hysteropexy for prolapse and procidentia.

Among conditions that allow intercourse but interfere with ascent of the spermatozoa, Dr. Giles mentioned under-development of the uterus, in which condition the prognosis depended mainly on the patient's age, anteflexion of the uterus, and stenosis of the external os. If a proper dilatation of the cervical canal were carried out, especially if followed by the insertion of an intra-uterine stem for a fortnight, the chances of subsequent pregnancy were very good.

Retroversion of the uterus was another condition unfavourable to conception, but not definitely preventing it. In atresia of the os externum prognosis was hopeless without treatment and not very good with it. As a rule, such atresia was the result of inflammatory conditions, which were likely to have other bad effects on the uterus besides closing its orifice. Nevertheless, in Dr. Giles's opinion, an attempt should be made to restore the patency of the canal. Polypi, fibroid and mucous, and submucous fibroids were in nearly every case curable, and prognosis varied with the gravity of the operation required. In endometritis conception was prevented probably by the injurious effect of the discharge on the vitality of the spermatozoa; where conception occurred the mucosa was in some cases not healthy enough to harbour the oösperm and miscarriage followed. The prognosis after curetting was good. In cases of mild salpingitis without occlusion of the tubal ostia, conception could take place, and the sequel was probably often a tubal pregnancy. However, it might be presumed that uterine pregnancy also followed. When salpingitis with occlusion was present conception was impossible. Where there had not been extensive suppuration or damage to the tubes an artificial ostium could be made by making an incision in the tube near the ovary and oversewing the edges. The prognosis should be very guarded.

Dr. Giles then mentioned certain methods of treatment that have a place when the cause of sterility lies with the man, and, in conclusion, laid special emphasis on the importance of considering the possible responsibility of the husband; on the folly of promising a successful issue as the result of treatment, for though we might secure correct anatomical conditions, we could not control their physiological working. The idea that every sterile woman should be curetted ought to be discouraged; in fact, no operation on a woman should be undertaken before the condition of the husband had been ascertained.

Discussion.

The PRESIDENT congratulated Dr. Giles on his paper, and emphasised the importance of the subject from the personal and racial standpoint.

Dr. R. A. GIBBONS agreed with Dr. Giles on the difficulty of collecting reliable statistics. When Matthews Duncan made his estimates the so-called Malthusian methods were not so widely used. Incidentally, Dr. Gibbons reminded the section that Malthus had spoken of war, pestilence, and famine as natural checks to over-production, and his advice had been that those who could not afford to have children to refrain from marriage, not to use contraceptives. Nowadays it was common for a young married woman to ask her medical man for advice as to the best method of preventing conception. The test of relative sterility was the rapidity with which conception takes place.

Dr. Gibbons had made confidential inquiries in 120 marriages. In 100 cases preventive measures had been used at one time or another, and the number of children was well under 2 per marriage. A declining birth-rate was a disastrous thing for a nation. In Paris some time ago the birth-rate was 104 in the poorer quarters and only 34 in a rich quarter of the city; in London comparative figures had been given as 195 and 63 in poor and rich quarters. These and similar figures showed that women living in comfort and luxury did not want to be bothered with confinements. It had been said that the degree of sterility could be regarded as an index to the morals of a race. Congenital sterility was rare, but the number of children born in England was decreasing. It had been estimated that one-third of the pregnancies of several great cities abroad aborted. Dr. Gibbons quoted figures given by Douglas Wright and Amand Routh to show the high percentage of abortions and stillbirths. In his opinion it was the duty of medical men to point out to the public that physiological laws could not be broken with impunity. It had been observed that if the doe were withheld from the buck at œstral periods atrophy of the ovary took place. In this connexion Dr. Gibbons recalled a large number of patients who had used contraceptives in early married life, and subsequently had longed in vain for a child. This applied also to those who had decided after the first baby to have no more children, and had subsequently regretted their decision.

Dr. MALCOLM DONALDSON expressed his appreciation of Dr. Giles's paper. He was most interested in cases of sterile women who proved normal on physical examination, and their husbands also, and wished Dr. Giles had spent more time on the discussion of these cases. Dr. Donaldson had examined nine women on 22 occasions to see how far up the canal spermatozoa could be traced, without getting conclusive results. Mr. Kenneth Walker had coöperated with him by examining the husbands. Dr. Donaldson asked Dr. Giles whether he considered that estimation of the acidity of the cervical discharge would be useful, and whether he had tried passing oxygen through the uterus to see whether the tubes were patent. He had thought that everyone nowadays examined the husband before submitting the wife to operation, but he had recently found aspermia in a husband whose wife had given a history of two curettings.

Mr. KENNETH WALKER spoke of the results of examinations of men. The statistics of male sterility recorded varied from 18 to 50 per cent. His own series was not really sufficiently large to speak about, but he wanted to emphasise the fact that a large number of men were relatively sterile. Spermatozoa were sometimes scanty in number, and in other cases were of abnormal shapes and sizes, or had more than one head. Occasionally signs of old inflammatory trouble could be detected in the prostate, or crystals of cholesterin in the semen. In 60 per cent. of the cases, where no definite physical abnormality was found in the wife, he would be inclined to blame the husband, and in another 30 per cent. something could be found wrong, enough to say that the man was not quite normal. The genito-urinary surgeon knew very little about the function of the prostate and the seminal vesicles. If the vesicles alone were excised the male remained fertile, also if the prostate was excised, but in the absence of both prostate and vesicles he was sterile. This subject had been very thoroughly investigated in rats. Even if spermatozoa were found in the semen the fault might still lie in the accessory glands of the husband. Detailed and careful overhauling of the husband was needed before it could be assumed for certain that he was not at fault.

Dr. HERBERT SPENCER expressed his agreement with Dr. Giles's condemnation of the operation for an artificial vagina. He disagreed with him on the subject of fixation of the uterus for prolapse and considered that this operation ought to be expunged from the list of operations performed. He was not satisfied with the results of dilatation of a pinhole cervix, and had had better results with Pozzi's operation. He agreed as to the number of women who, after using contraceptives at first, later wanted a child and did not have one. Many of these had used quinine pessaries. Possibly a thickening of the mucous membrane or other alteration followed the use of these pessaries.

Professor LOUISA MCILROY regretted that Dr. Giles had in his interesting paper dwelt so much on pathological conditions. In her opinion we had almost exhausted the pathology of sterility, and the most interesting cases were those which showed no physical signs. The really important aspect of the subject was the consideration of the biological and physiological factors influencing fertility. Professor McIlroy rejoiced that Dr. Giles had not laid excessive emphasis on syphilis as a cause for repeated abortions, as this idea was, in her opinion, much overdone at present. A positive W.R. was not of much value in pregnancy. Certain work on the ductless glands had convinced Professor McIlroy that the ovum was a ductless gland; possibly other ductless glands might have an inhibitory effect on the ovum. In cows a persistent corpus luteum was supposed to prevent pregnancy, and farmers had attempted massage through the vagina. Professor McIlroy deplored the amount of time spent on attempting to cure sterility when contraceptives were so widely used. She said that the fact that neuroses were largely the result of the use of contraceptives should be made widely known, and also that in women the maternal passion was even stronger, though it might develop later, than sexual passion, and would ultimately demand satisfaction.

Dr. J. S. FAIRBAIRN congratulated Dr. Giles on having made the subject as little barren as possible. Professor Arthur Robinson had recently given the results of an investigation into sterility in animals. Among stallions 30 to 40 per cent. of the matings proved sterile. In ferrets a large percentage of fertilised ova became degenerate and did not proceed to normal development. The deduction to be drawn from these investigations was that abortion was often wrongly ascribed to endometritis, &c., in the human subject.

Reply.

In reply Dr. GILES endorsed Dr. Gibbons's remarks as to the great unhappiness resulting from deliberately childless marriages, and had always warned patients of this. He believed that quinine had a permanently bad effect. Those who waited to have a child for a convenient season often laid up trouble for themselves. On the question of fibroids he had come to the conclusion that these were not a cause but in a sense a consequence of sterility. Women who were subjected to sexual excitement with no physiological outlet appeared to have a tendency to develop fibroids. He would like the opinion to go forth from the section that the use of contraceptives was a bad thing. He agreed with Dr. Donaldson and Professor McIlroy that the apparently normal cases were the most difficult, but he had not said more on this subject because of our profound ignorance thereon. As to the reaction of the cervical secretion the normal reaction was of course alkaline. After endometritis it might become acid, and spermatozoa could not live in an acid medium. He had not tried the injection of oxygen for diagnostic purposes. He was interested in Mr. Kenneth Walker's remarks as to the large percentage of defect traceable to the male partner. It must be borne in mind that the success of treatment was difficult to estimate, since in some cases after many years conception occurred spontaneously. He had heard of one case where pregnancy was reported to have occurred after 20 years of sterility. Changes in habits were also a factor; too great frequency of intercourse might prevent conception, whereas rest and change often proved beneficial.

LIVERPOOL MEDICAL INSTITUTION.

THE last ordinary meeting of the session was held on April 28th, Dr. J. E. GEMMELL, the President, in the chair.

Dr. FRANK H. BARENDT read a note on the Antiquity of Syphilis.

Dr. ISAAC HARRIS read a paper on the

Value of the Electro-cardiograph in Diagnosis and Prognosis.

Whilst the electro-cardiograph had its limitations, there were, he said, a great number of affections of the myocardium which could only be diagnosed by means of it. The practical significance was indicated of an inverted T in the second lead, of abnormal Q.R.S. complexes and other cardiographic aberrations. A case of auricular fibrillation complicated by degeneration of the heart muscle was given as an illustration of the value of electro-cardiography as guide in treatment. Digitalis was to be avoided in such a case which could not be diagnosed without the cardiograph. In regard to the Adams-Stokes syndrome, Dr. Harris pointed out that in his experience heart-block, partial or complete, uncomplicated by degeneration of heart muscle, never gave rise to the syndrome, while whenever it appeared degeneration of the muscle was found. Hence Mackenzie's contention that the syndrome was due to a sudden transition from normal to ventricular rhythm was considered untenable. The prognosis of these cases was, as a matter of fact, much worse than that of ordinary block.

Dr. JOHN HAY said that it was essential to understand what an electro-cardiogram represented. It gave in graphic form the variation in electric potential associated with each systole of the heart and nothing more. If for any cause any portion of the heart beats abnormally there was a change in the curve. Fibrillation, flutter, extrasystoles, heart-block, relative hypertrophy of either ventricle all presented their characteristic electro-cardiogram because some portion of the heart was contracting in an abnormal manner. A recognition of these variations made diagnosis certain, and brought some accuracy into prognosis. Variations in the ventricular complex were significant of myocardial damage—i.e., arborisation-block. Data were being collected of patients presenting bizarre forms of Q.R.S. complex. At the Royal Infirmary cases of auricular fibrillation in which this unusual form of electro-cardiogram was present were being observed in regard to the course of the disease. In patients suffering from fibrillation there was a small percentage in whom ectopic beats occurred; the prognostic import of this abnormality was not yet settled, though it was considered to indicate a serious outlook.

Mr. FRANK JEANS read a note on the Uses and Limitations of the Cystoscope, with special reference to conditions in which the cystoscope was the sole method of diagnosis.

Mr. G. P. NEWBOLT described a case of Cyst of the Brain occurring in a youth aged 17.

Correction.—In a report of a paper read by Dr. Jane Walker before the London Association of the Medical Women's Federation on Tuberculosis in Children of School Age, which appeared in THE LANCET of April 23rd (p. 862), the following sentence occurs: "From 1914 to 1919 at the East Anglian Sanatorium 62 per cent. of the 807 children had T.B. in the sputum and of these 56·4 per cent. died." This should read: "From 1914 to 1919 at the East Anglian Sanatorium *68, or 8·4 per cent.*, had T.B. in the sputum and of these 35, or 56·4 per cent., died."

THE SOUTHERN UNIVERSITIES OF IRELAND AND THE ELECTIONS.—Our Dublin Correspondent writes: "It is symptomatic of the lack of interest shown by the Irish public in the elections to the Southern Ireland Parliament that, writing only a few days before the nominations, one cannot discern with any certainty what candidates are likely to present themselves in the two university constituencies. Dublin University and the National University are each entitled to elect four members. In regard to the former, three or four names have been mentioned in the press, of whom some at least could hardly be regarded as serious candidates if the election were a serious affair. Among them no medical name occurs, nor have I heard of any medical man contemplating candidature. In the National University it is understood that Professor John McNeill, the present member for the University, will be a candidate, but it is not known who his colleagues will be, or whether there will be a contest. The likelihood of a contest is much diminished by the decision of Mr. Dillon not to encourage Nationalists to seek election at present, but there may be some independent candidates."

Reviews and Notices of Books.

DISEASES OF THE SKIN.

By J. M. H. MACLEOD, M.D., F.R.C.P. London: H. K. Lewis and Co., Ltd. 1920. Pp. 1307. £3 10s.

Dr. MacLeod has dedicated his book to his colleagues in dermatology, and the appreciation with which it will surely be received by them should compensate him for the infinite pains he has bestowed upon it. We think it may rank among the most authoritative text-books of dermatology that has yet appeared in the English language; it is certainly the most readable English modern work. It is unlikely that the charm and the vivid word-pictures which characterise Darier's "Précis de Dermatologie" will ever be reproduced; this stands alone and hardly admits of comparison. But Dr. MacLeod's book resembles the Précis in this respect—while his descriptions are admirably succinct, they are not written in the text-book style which makes consecutive reading almost an impossibility. The author admits that he has been compelled to omit a good deal of the historical side of the subject, and to restrict the bibliographies; at the same time he has given us an excellent short account of the history of leprosy. The bibliographies, if not complete, are at any rate very useful, and, as a rule, the most important references to the literature of the various diseases are given. Curiously enough, soft sore is not dealt with except in the discussion on the diagnosis of genital chancres, but this is not a very serious omission.

No text-book can be quite up to date, but this volume can be little criticised in this respect. A few important sections might have been modernised. For example, in that dealing with oriental sore the treatment is said to be "unsatisfactory," and, while Low's method of applying an ointment of tartar emetic is given, administration of antimony by intravenous injection is not mentioned, although Ferra, of Brazil, used this method successfully several years ago. Again, in the description of xanthoma, which is included in the chapter on "Pseudo-neoplasms of the Skin," no reference is made to the work of Pinkus and Pick, and of Chauffard and his assistants on cholesterinæmia, nor is the fact mentioned that in xanthoma multiplex, at any rate, the amount of cholesterin in the blood is greatly in excess. Describing herpes zoster, Dr. MacLeod says: "Should suppuration occur, the neighbouring lymphatic glands generally become enlarged—a feature which has been noted even in cases in which the lesions were uncontaminated by pyogenic micro-organisms;" and Dr. Henry Head, in a classical article on zoster, states that "in most cases the contents of the clear vesicles become turbid. Possibly it is in connection with this pus formation that the lymphatic glands that drain the affected tract of skin are in the majority of cases enlarged." It is curious that these two accurate observers should apparently not have noticed that the adenitis associated with herpes is such an early symptom that it certainly sometimes, if not always, precedes the appearance of the eruption.

We are surprised, too, to find in the section on pruritus ani that Murray's view that the actual pruritus is due to infection of the skin with the *Streptococcus fæcalis*, whereas local disorders of the rectum, threadworms, &c., are only predisposing factors, is summarily dismissed as untenable, and treatment by vaccines as unreasonable. Bassler entirely supports Murray's work, and considers that autogenous vaccine treatment is the most valuable method in cases in which the pruritus persists after any local abnormality has been corrected by operation or otherwise, and, according to him, failure with vaccines is usually due to ignorance of the technique and of the dosage required. The last chapter is devoted to tropical diseases of the skin, upon which the author is a recognised authority, and it is to be noted that, in discussing the ætiology of pellagra, he seems rather to favour the views of Sambon, which, in the light of Boyd's work among Turkish prisoners of war, to which no reference is given, and of the observations of American workers on the subject, can hardly now be seriously considered.

But, in criticising such minor points as these, we do but emphasise the general excellence of Dr. MacLeod's work; his clinical and histological descriptions are clear, his discussions of the ætiology of diseases of doubtful causation are eminently fair, and the sections on treatment are unusually detailed and helpful. We were particularly impressed by the sections on syphilis and leprosy. The illustrations have been carefully selected, and are almost uniformly good, and we gather that the publishers have spared no pains to assist Dr. MacLeod in the great task which he has so successfully accomplished.

FEEBLENESS OF GROWTH AND CONGENITAL DWARFISM.

By MURK JANSEN, O.B.E. London: Henry Frowde and Hodder and Stoughton. 1921. Pp. 82. 12*s.* 6*d.*

Dr. Murk Jansen's writings are suggestive, even when we do not quite see our way to full agreement. In this book he has endeavoured to show the causative relations between several conditions, many of them ill-defined, and all of them obscure, and to link these together as examples of the injurious effects of noxious influences acting on the growing body under different circumstances and at different periods. In the first part, dealing with "feebleness of growth," the author points out that this result may follow from any injurious agent acting on the developing body, and that it is proportional, not only to the intensity of this agent, but to the rapidity of growth both of the individual and of his various parts. Dealing mainly with the skeleton, he goes into physiological details of bone formation, and shows how these functions may be affected. We do not think that there will be serious objection to the general "laws" which Dr. Jansen has laid down to explain the affections with which he is dealing, and which enable him to bring them together as a series in harmonious conjunction. The few paragraphs devoted to growth feebleness in the soft parts might prove of suggestive value to clinicians other than the orthopædic surgeon.

In the second part of this short treatise (Congenital Dwarfism), however, we must join issue with the author on some of his suppositions. We have no desire to lay stress on what are probably inaccurate dates in organogeny, for these are easily adjusted, but we cannot help feeling that the author is mistaken in his views when he refers the physical abnormalities in achondroplasia, anencephaly, &c., to the mechanical action of an imaginary small amnion. The amnion has always been liable to indictment for all sorts of offences, and amniotic bands are a regular refuge for many ætiologists in their search for causes. It cannot be denied that such bands occur, but they are rare, and any connexion with deformities has not, we believe, yet been shown. In many cases an "amniotic band" is credited with an effect it could not possibly produce, even if it were present, and the presence of an efficient cause of both the band and the abnormal development, such as uterine disease, is overlooked. Dr. Jansen, however, does not depend on such accessory structures in his ætiological conceptions, but postulates a shortness or want of growth of the amnion, probably only temporary in nature, to account for the interference with nutrition which he recognises in his cases. We do not believe that any practical human embryologist would admit for a moment that the embryonic amnion with which he is acquainted could, under any circumstances, oppose a barrier to the growing power of the embryo, or interfere with its blood-supply, in the way imagined by Dr. Jansen. It may be pointed out that one of the commonest and earliest signs of a pathological ovum or embryo is enlargement of the amniotic sac, and diminution in its size has not, so far as we know, been recorded. On the other hand, although it may not bear directly on the question, it is of interest to recall that in some of the lower vertebrates, the embryos develop under the pressure of a thick resistant zona, so that they are flattened out and deformed by being pressed down to one side; yet when the membrane gives way they are found unaffected and pursue their course, straight, but otherwise as before. We do not see the necessity for the postulate. Surely the noxious agents which can be held responsible for upsetting normal nutrition may be thought potent enough to cause local emphasis, if periodicity is granted, without calling in the aid of probably impossible factors.

Dr. Jansen works in his theories most ingeniously with the facts, but, as we consider that the explanations are based on a wrong assumption, we cannot allow our admiration to alter our belief that the embryological evidence is against him. Nevertheless, we have no hesitation in recommending all those who are interested in thoughtful contributions to the pathology of deformities to read this book. When they have finished it they will probably have a better grasp of the subject-matter of the work, whatever views they may hold about the cast-iron potentialities of the amnion.

RADIOGRAPHIC TECHNIQUE.

By T. THORNE BAKER, A.M.I.E.E. London: Constable and Co., Ltd. 1921. Pp. 196. 15*s.*

THIS is a small volume devoted almost entirely to the photographic side of radiography, and is evidently written by one who is thoroughly conversant with all the necessary photographic processes that go to make the perfect radiograph. The author's assertion that the photographic knowledge of many operators is lamentably deficient is probably true, and it is to meet this difficulty that the present volume is written. A preliminary chapter is given on the installation itself, to aid the user to locate faults, but the main object is to explain and instruct the operator in carrying out the dark-room processes, the proper management of intensifier screens, and such other details as help to make a radiograph pleasing to the eye as well as valuable in diagnosis. The two concluding chapters deal with industrial applications of radiography, which open up a new field to this branch of science.

MANSON'S TROPICAL DISEASES.

Seventh edition. Edited by PHILIP H. MANSON-BAHR, D.S.O., M.D. Camb., M.R.C.P. Lond. London: Cassell and Co. 1921. Pp. 960. 31*s.* 6*d.*

THE publication of the seventh edition of "Manson's Tropical Diseases," under the editorship of Dr. P. Manson-Bahr, provides a most comprehensive and up-to-date study of the vast field of tropical medicine. The subject-matter of the new edition is divided into eight sections and three appendices. Section I. embraces the wide range of tropical fevers and occupies approximately one-third of the whole volume.

The subject of malaria is elaborately dealt with. The whole question of quinine treatment and of the methods of administration is placed before the reader in a convincing and unbiassed manner. Due weight is given to quinine prophylaxis, but the importance attached thereto previous to the war appears to have been excessive. Certain points connected with the epidemiology and endemiology of malaria are emphasised as requiring further elucidation and explanation, in particular "the exemption of certain islands from malaria, even though in the midst of an archipelago of malaria-haunted islands"; also the existence of malaria-free districts surrounded by highly malarious country and abounding in Anophelinæ. It is suggested that hyper-parasitism or the destruction of the plasmodium by some other kind of parasite, such as the "black spores" described by Ross, may account for such anomalies. A lucid and interesting account is given of blackwater fever, the ætiology of which must still be regarded as unsettled. New work on trypanosomiasis is included. The question of the identity of *T. rhodesiense* and *T. brucei* is still much in dispute, as also is the question of the harbourage of *T. rhodesiense* by big game. This point is important as it has been raised in connexion with the desirability of game extermination, as a means of prophylaxis in addition to the clearing of areas infested by *Glossina palpalis* and *morsitans* in the regions respectively affected by *T. gambiense* and *T. rhodesiense*. It is curious that antimony tartrate and atoxyl, though advocated in the treatment of *T. gambiense* infections, are relatively powerless against *T. rhodesiense*. The forms of leishmaniasis, kala-azar, oriental sore, and *L. americana* are fully described with coloured drawings of the parasites concerned. Remarkable results appear to have followed the adoption of intravenous antimony tartrate treatment.

In connexion with yellow fever the recent work of Noguchi and the discovery of the leptospira conveyed by *Stegomyia fasciata* promises to prove of the highest importance. Recent researches into Rocky Mountain fever and typhus fever—in the case of the former by Ricketts, and the latter by Arkwright, Bacot, and others—are described, and lend much hope to the discovery of the real causes. In Rocky Mountain or spotted fever the so-called Rickettsia bodies are the supposed virus of the disease, conveyed by and found in the tick *Dermacentor venustus*. In typhus fever and trench fever similar bodies are met with; and termed *Rickettsia prowazekii* they are found in lice infected with typhus blood. A full account is given of relapsing fever. The chief transmitting agent of the North African and European forms of the disease, from the most recent evidence, is in all probability the louse (*Pediculus humanus*), whereas in Central Africa and Persia the ticks *Ornithodorus moubata* and *Argas persicus* are concerned as carriers. Considerable space is devoted to the subjects of plague, Malta fever, and the enteric group of fevers. The Marris atropine test receives a full description, and is noted as "the most important contribution made during the war to the diagnosis of enteric fevers." Section I. concludes with a valuable summary of the diagnosis of fevers in the tropics.

Under Section II. are included "General Diseases of Undetermined Nature"—i.e., beri-beri, epidemic dropsy (war œdema), pellagra, and scurvy in the tropics. The food-deficiency and other ætiological theories are fully discussed. Under Section III. are described Abdominal Diseases. A graphic account of cholera and its treatment by Rogers's intravenous injection of hypertonic saline solution combined with injections of atropine, and also by Cox's method of slow intravenous injections of isotonic saline fluid is given. The dysenteries, both bacillary and amœbic, are considered in a full and admirable account. Under Section IV. are described the infective granulomatous diseases, including, in particular, leprosy and yaws, both of which are graphically dealt with. In the treatment of leprosy prominence is given to the value of chaulmoogra oil, of the gynocardate and morrhuate of soda advocated by Rogers and Muir, while the more recent soya bean oil, which is still on trial, is noticed. Section V. includes the important group of animal parasites and associated diseases. In the treatment of schistosome infestations the value of intravenous injections of tartar emetic is mentioned as having been placed on a sound basis by Christopherson. The important subject of filariasis is even more comprehensively dealt with than in the previous edition. The succeeding chapters of the helminthological section deal fully with fluke parasites of the lung and liver in paragonimiasis and clonorchiasis and the many forms of infection by intestinal parasites, in particular ankylostomiasis. Section VI. is devoted to diseases due to poisons, including the various forms of snake-bite, and an account is given of the vomiting sickness of Jamaica, the cause of which, long obscure, has been clearly determined by the able work of Harold Scott to be due to ackee poisoning. In the two concluding sections are described tropical skin diseases and local diseases of uncertain nature, such as craw-craw, chappa, climatic bubo, goundou, and ainhum.

The value of the new edition is much enhanced by the important and practical information contained in the three appendices occupying the last 200 pages under the headings of Medical Protozoology, largely the work of Dobell; Medical Helminthology, Entomology, &c., and a very complete account of laboratory methods as applied to clinical medicine in the tropics. The last will undoubtedly prove of the greatest use not only to those engaged in practice in the tropics and in the Colonial Medical Service, but also to the student of tropical medicine at home.

The outstanding merits of this edition, retaining, as it does, the lucidity of expression and charm of style of previous editions, will ensure it a large circle of readers both at home and in the tropics. The type and general arrangement of the various subjects are excellent, and the numerous coloured plates are beautifully executed.

AIDS TO DENTAL SURGERY.

Third Edition. By DOUGLAS GABELL. London: Baillière, Tindall, and Cox. 1921. Pp. 192. 3*s.* 6*d.*

THE student will find this little book of some value if he will use it as an aid to revising his work and not rely upon it for the purpose of cramming for examination. The author might have added to the usefulness of the book by bringing it thoroughly up to date and extending certain sections—for example, that dealing with the relation of dental sepsis to other pathological problems. In the introduction attention is directed to the necessity of ascertaining all the facts of a case by systematic examination, and a clear account is given of the way in which this examination should be conducted. There is a useful section on the hygiene and care of the teeth and mouth. Hæmophilia is not mentioned—probably an oversight.

AN ATLAS OF NORMAL LABOUR.

With an Appendix showing Sylvester's and Schultze's Methods of Artificial Respiration. By G. DRUMMOND ROBINSON, M.D., B.S. Lond., F.R.C.P., Obstetric Physician to the Westminster and West London Hospitals. London: William Heinemann, Ltd. 1921. Pp. 104. 25*s.*

THIS Atlas consists of a number of photographs made from kinematograph films demonstrating the processes of normal labour in the living subject, and from drawings which the author had prepared for teaching purposes. It is obvious that it is only possible to employ the kinematograph to a very limited extent in showing the various processes of parturition, and that such photographs can only be obtained of the latter part of the second stage and of some part of the third stage of labour. The great majority of the plates, therefore, represent photographs of drawings of what the author, no doubt quite correctly, conceives to be taking place during labour. The actual kinematographic photographs of the stages of labour which it is possible to represent in this way are very interesting and valuable, but the question must arise as to whether the results are worth the trouble and expense entailed. Nothing can be photographed in a case of labour which cannot be equally well seen, and observation at the bedside must always be much more valuable than any series of drawings or photographs. The Atlas is, however, an interesting production, obviously compiled only at the expense of much care and trouble.

THE EXTRA PHARMACOPŒIA.

Sixteenth edition. Vol. II. By W. H. MARTINDALE, Ph.D., and W. WYNN WESTCOTT, M.B., D.P.H. London: H. K. Lewis and Co. 1921. Pp. 688. 17*s.* 6*d.*

THE second volume of Martindale and Westcott follows rapidly on the first; it has grown largely in bulk and usefulness since the last edition five years ago. The scope of the volume is difficult to express in a few words. Primarily it consists of analytical addenda to the materia medica described in the first volume. These are almost indispensable to anyone who dispenses his own physic, but they should be appreciated, too, by all who desire to prescribe quickly, pleasantly, and effectively. A knowledge of the manners and habits of drugs greatly enhances the range of intelligent medicamentation. In this section appear in the present edition interesting notes on aspirin, cinchona, and digitalis. Around this primary nucleus has grown up layer by layer a number of sections on animal organotherapy, on physiological methods of assay, on radio-active substances, and on the antiseptic power of disinfectants. The information may be available elsewhere but only by stress and toil; here it is accessible, precise, and properly documented. Notes on the analysis of water, milk, butter, and the like, make the book welcome in any laboratory, large or small. Bacteriological and clinical notes on special diseases appeal to practitioners of medicine whose information on, say, leprosy or leishmaniasis is not quite recent and methodical. There is a large but not quite exhaustive list of proprietary medicines and a glossary of foreign words used in pharmacy, which contains the only piece of careless proof-reading in the whole work. An index is now added to include both volumes of the Extra Pharmacopœia. It is not easy to commend this book to anyone unacquainted with it without appearing to exaggerate. Martindale and Westcott picks up many of the fringes of medicine and makes them neat and tidy. Lacking it, the practitioner can hardly feel professionally quite well-groomed. The price has risen from 7*s.* to 17*s.* 6*d.*, but value is offered for the extra half-guinea.

JOURNALS.

Journal of Laryngology and Otology. March and April, 1921. Vol. XXXVI., Nos. 3 and 4.—In the March number Professor Ross Hall Skillern, of Philadelphia, discusses the operative treatment of ethmoidal suppuration. He finds that patients are frequently made worse by indiscriminate ablation of ethmoidal cells, and that in most cases the best results are to be obtained by preliminary removal of the middle turbinal, and then, after healing has occurred, by carefully following the pus to its source; good stereoscopic skiagraphs are of material assistance.—Mr. James Harper describes a method of partial thyroidectomy by which the gland is shelled out of its capsule with the finger; he claims that there is no shock nor risk of post-operative hæmorrhage or of injury to the recurrent nerve, and that it is never necessary to ligature an artery.—Mr. Andrew Campbell describes Bezold's method of treating chronic suppuration of the middle ear by intratympanic syringing, inflation, drying, and the insufflation of boric acid.——The April number contains a description of four cases of thrombosis of the cavernous sinus, by Dr. Ritchie Rodger.—Mr. Layton reports a death after tonsillectomy in a man aged 32 years; he had had the fauces anæsthetised two and a half hours before by injection of novocaine and adrenalin, and the pillars were sutured at the close of the operation on account of persistent oozing, but bleeding recurred and was finally arrested about 11 P.M., and the patient died at 4.30 on the following morning; it is doubtful whether death was due entirely to hæmorrhage as there was some post-mortem evidence of pulmonary embolism.—Dr. J. N. Roy, of Montreal, describes the successful removal by œsophagotomy of a foreign body which had remained in the gullet for nearly 14 months.—Mr. W. M. Mollison contributes a study of the tonsil as a focus of infection in chronic arthritis.

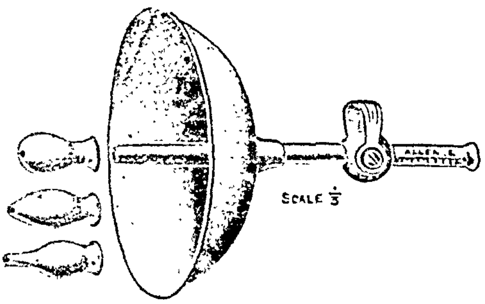
Archives of Radiology and Electrology (January, February, and March).—Recent issues present many subjects of interest. In the January number Dr. A. E. Barclay points out a danger attending the use of the Coolidge tube for screen examinations, while some studies in gastro-intestinal diagnosis are contributed by Dr. R. Knox.—Sir James Cantlie describes an X ray motor ambulance for use at home and in tropical countries that is likely to be of great value. The question of pastilles and their colour measurement is dealt with by Messrs. Donnithorne and Baker, and emphasises the conditions in which these should be used if reliable results are to be obtained.——In the February number Dr. Gosta Forssell, of Stockholm, contributes a valuable paper on the Differential Diagnosis of Tuberculosis in Bones and Joints, which is admirably illustrated with a series of splendid radiographs.—A sketch of the History of Electrotherapy by Dr. Hector A. Colwell is evidence of much painstaking research, and is accompanied by many illustrations of persons, appliances, and methods that have made the history of this interesting subject.——Dr. Forssell's paper on Tuberculosis is continued in the March number, and Dr. J. Neil Leitch refers to some uses of the infrequently interrupted faradic current, which seems to have a special value in cases of incontinence.—The principle of the Bucky Diaphragm for radiography of the thicker parts of the body is described by Dr. H. E. Potter. —The usual sections are devoted to reviews, notes, and abstracts.

New Inventions.

URETHRO-VESICAL MEDICATION.

(1) *An Improved Irrigator Handle.*

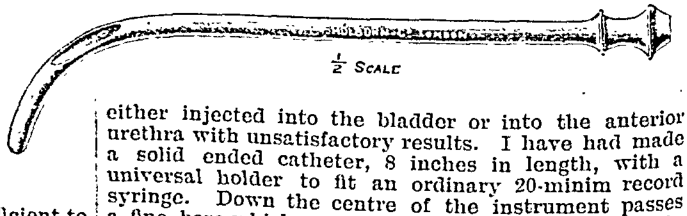
THE advantage of the irrigator handle herewith illustrated is that by means of a special stopcock inserted in the stem the flow can be regulated from a drop to a force sufficient to allow the fluid to enter the bladder, only one hand being required for this manipulation. It thus does away with the necessity for any clip upon the rubber tubing. A dome 4½ in. in diameter, sufficient to protect from splashing, is soldered on to the stem at a distance from the rubber tubing, to permit of the instrument being supported on the palm of the hand and the flow controlled by compressing the rubber tubing between the thumb and index finger, as some operators desire, yet the stream can immediately be shut off by closing the stopcock with the thumb of the same hand. The stem projects from the dome a distance sufficient to give a good view to the operator when the nozzle is inserted. The nozzles, metal or rubber, are made in three sizes to suit a small, medium, or large meatus. They block the meatus but do not enter the urethra. They are easily sterilised and extremely durable.



The handle is made by Messrs. Allen and Hanburys, Ltd., 48, Wigmore-street, London, W.

(2) *A New Syringe for the Treatment of the Posterior Urethra.*

In the treatment of chronic posterior urethritis or the sexual neuroses one often wishes to instil a medicament into the posterior urethra, and Ultzmann's syringe is used for that purpose. All operators are aware of the difficulty of localising the instillation to the spot desired, and unless considerable skill is used the fluid is either injected into the bladder or into the anterior urethra with unsatisfactory results. I have had made a solid ended catheter, 8 inches in length, with a universal holder to fit an ordinary 20-minim record syringe. Down the centre of the instrument passes a fine bore which opens into a hollow notch, 1 inch in length, placed on the convex side of the catheter curve. When the instrument is in situ the verumontanum projects into this concavity and so can be treated; on slightly withdrawing the instrument the remainder of the posterior urethra can be dealt with.



The instrument is made by the Holborn Surgical Instrument Co., Ltd., Thavies Inn, London, E.C.

Harley-street, W. M. W. BROWDY, M.B., Ch.B.

THE LANCET.

LONDON: SATURDAY, MAY 14, 1921.

The Teeth of the Nation.

The Dentists Bill was introduced by Sir ALFRED MOND on Thursday, May 5th, and read for the first time. Although it is a mere truism to say that to have sound teeth is one of the conditions of good health, few of the public, we imagine, realise how accurately the quality of the teeth is an index of the soundness of general hygienic upbringing, and how badly, judged by this criterion, the British nation would emerge from the ordeal. It cannot be claimed in mitigation that we have been kept in ignorance of this alarming state of affairs, for has not Sir GEORGE NEWMAN repeatedly warned us in his illuminating reports to the Board of Education, and with all the weight and authority of statistical evidence out of the mouths of some 8,000,000 school children? And did not the medical examination of recruits for our recent armies also prove beyond any possible question that as far as the teeth are concerned we are a sick nation? The Ministry of Health undoubtedly realises its responsibilities in this regard. And this is well, for in no department of medicine is quackery more rife than in that which is concerned with the care of the teeth. But the problem of the prevention of dental caries will not be solved by setting up a State Board of Dentistry or by the maintenance of a register, be the latter never so carefully kept. Both these innovations will help in setting our house in order, but public coöperation is needed.

With the best will in the world, and without considerations of expense, the care of the nation's teeth is a large task. There are not enough dentists in the United Kingdom to repair all the damage which has been inflicted by neglect, so that the interests of the public will certainly not be served by any drastic measures which deprive a large section of the practising dentists of their chance to pursue their calling. The views of the Dentists' Committee and of the British Dental Association on the rights of various practitioners to be included in the registry, should the new Bill be placed on the statutes, will be heard with respect. But these bodies must inspire the sense of Parliament to protect the public from fraudulent practice—that must be the main objective. Good teeth do not depend solely on the skill of the dental practitioner; his services are mainly essential to make amends for failure in prophylaxis. Well-made and well-mineralised teeth should not stand in need of the benefit of dentistry, at any rate until after middle age. What we want to know is what are the conditions on which the development of healthy teeth depend. We are just beginning to understand some of the essential factors on which nutrition is based, and sound general nutrition is one, perhaps it is the chief, condition on which the development of good teeth depends. We recognise, indeed, that in the main the problem is one of dietetics, not only in the child during the whole of the time the teeth are forming in the jaws, but also in the mother before the child is born. While not accepting without reservation the theory of the school which explains both carious teeth and the larger problem of rickets on the grounds of vitamin starvation, it must be admitted that deprivation of accessory food factors seems established as one of the causes which lead to malnutrition and defective teeth. It would be fatal to allow an attractive theory to obscure the clearness of our judgment, or to tempt us to stake too much on a speculative hypothesis. The problem of rickets or that of carious teeth is not going to be solved by the distribution of cod-liver oil, the prevention of food adulteration, or a drop in food prices. We must promote the development of good teeth in the light of knowledge we already possess. The difficulty is to disseminate this information sufficiently widely in the quarters where ignorance prevails.

Much can be done by attending not only to the diet but also the general hygienic management of the mother during pregnancy and of the child after. Breast-feeding is clearly of first-rate importance, while, after weaning, the diet must be adjusted to physiological requirements as regards quantity no less than quality, and as regards general balance no less than as regards the special balance of the constituents. The development of the jaws by adequate mastication appears no less valuable than nose-breathing, while the toilet of the nose is just as necessary as the hygiene of the mouth. Among indirect causes of dental caries must be included general infection, such as measles, unhealthy tonsils, and oral sepsis, all of which tend to produce either a condition of general acidosis or some local condition of acidity which demineralises the teeth. Well-formed and well-mineralised teeth are not easily affected by passing conditions of acidity, either of the mouth or of the tissue juices; but when acidity is chronic or long-continued the teeth are liable to suffer, especially if badly made. Enlightened public opinion and the spread of knowledge are the only reliable prophylactics against risks arising from so many sources. It would be disastrous to rely only on skilled and registered dentistry to save us from the Nemesis of mismanaged infancy, and every scientific dentist knows this to be so. Welfare centres, health visitors, and our national societies for the prevention of infant mortality have done, and are doing, stalwart service in instructing the mothers of the rising generation in some of the elementary laws of dental prophylaxis. Much, however, still remains to be done. The Dentists Bill may be felt to press hardly on the present registered constituency, who have all our sympathies; but inasmuch as it eliminates quackery it will promote public effort.

Aphasia.

The study of thought and speech presents an interesting example of the manner in which knowledge grows. Different investigators approaching a problem along different routes observe facts, devise terminologies, and evolve theories to explain the phenomena. These researches appear for some time to have no tangible connexion or relation with one another until a bridge builder appears who tries to throw an arch from one to the other. Under the new stress a buttress of carefully fashioned theory may collapse and require rebuilding in the light of the newly won experience, or the whole may stand and the world be in possession of a new, illuminating conception. For 2000 years philosophers have reasoned about the phenomena of thought and speech; analysis and introspection yielded various explanations of the relationship between mind and body. Then came the period of the experimental method; on the one hand the phenomena of mind were studied by the psychologists, and on the other the anatomists and physiologists began building up a sure knowledge of the organ of mind. Medical men being necessarily observers of what amount to destructive experimental lesions carried out by Nature, it is natural that bridge-builders should be found working in their ranks.

Dr. Henry Head, in his recent papers,[1] has reopened the whole question of aphasia. He traces the modern development of our knowledge from Gall, with his six varieties of memory located in the frontal lobes, to the schematic explanations of Charlton Bastian and Wernicke and the attempt to make theory fit facts more closely, which was made by Marie. Dr. Head has devised a new method of examination of the aphasic, based upon the principle that the patient's power of response must be tested by a series of observations in which the same task occurs on two or more occasions. He claims that the observations made indicate that disorders in the use of language cannot be classed under the category of isolated affections of speaking, reading, or writing, nor can they be explained as due to the destruction of visual, auditory, or motor images. What is affected is essentially the ability to grasp the significance of symbols of all kinds, the power of "symbolic thinking and expression," so that even in "motor" aphasia, not only external speech, but certain aspects of internal speech are affected. As a result of lesions in different parts of the brain this power becomes dissociated in a manner analogous to the effect produced on sensation by lesions of the cerebral cortex; and Dr. Head distinguishes four main varieties of dissociation resulting in verbal, nominal, syntactical, and semantic aphasia. In verbal and syntactical aphasia it is the idea of the structure of the word which principally suffers both in external and internal speech; there is a defective conception of the structure and the rhythmic balance of the symbol. In nominal and semantic aphasia the ultimate significance, the full range of association, of the word is impaired or lost, so that the word cannot be used perfectly as a language symbol. He maintains that we have been led astray by Bastian and others, who based their work upon the theory that we think in words, while his results substantiate the teaching of Hughlings Jackson that it is the power to form propositions which is affected, and the more nearly a symbolic action approximates to a proposition the greater the difficulty it presents. A priori terms, such as "motor" or "sensory" aphasia, "alexia," and "agraphia" do not correspond to any actual discoverable functional categories; they should be abandoned, as should be all attempts to find any localisation for them in the brain.

At present Dr. Head has not indicated any localisation of the lesions producing his four varieties, and he modestly states that his results "are of no direct practical value to the physician"; but it has long been clear that our theories, based upon hypothetical "centres" for memories of images have been inadequate to explain the actual symptomatology of any patient, and destructive criticism based upon experimental evidence in conjunction with a new classification, running across the lines of the older theories, constitutes an important step. It means that we are enabled to study our patients from a new angle. If experience of his methods in other hands leads to confirmation of his results, and still more if he discovers to us a localisation corresponding to the new varieties of aphasia, Dr. Head will have placed a valuable diagnostic weapon in our hands. Until then we must rely upon the older methods which, although possibly based upon an incorrect psychological foundation, have nevertheless many clinical successes to their credit.

◆

Sterility and Abortion.

In his Sir John Struthers lecture[1] Professor Arthur Robinson offers a serious challenge to the current belief that sterility and prenatal death, and abortion resulting therefrom, are due to disease or abnormal environment of either parent. Defining prenatal death as the death of ripe extruded ova, or of the zygotes formed by the union of such ova with spermatozoa before the termination of the normal period of gestation, he proceeds to offer evidence that this is a frequent and regular occurrence in certain groups of healthy mammals under ordinary conditions. In order to prove whether the defect leading to death is germinal or parental in origin in any species, the ovum extrusion-rate and the actual birth-rate must first be ascertained in a satisfactory number of cases; the period, before or after fertilisation, at which prenatal death occurs—and if the latter, whether before or after the attachment of the zygote to the uterine mucosa—is also important. Professor Robinson's investigations on horses and ferrets, two very different groups of mammals, provide much, though not all, the data.

The records of the matings of 390 Clydesdale stallions with 28,241 mares, and of 43 thoroughbred stallions with 3640 mares were placed at his disposal. The mare ovulates at every heat period, whether inseminated or not. Since none of the mares died or were killed, the ovaries and genital canals could not be examined, and in these respects the history is incomplete. The average prenatal mortality of the Clydesdales during a period of six years worked out at 48 per cent.; the thoroughbreds during five years gave a prenatal mortality of 58 per cent. Of the ferrets, 165 only were available, but since the ovum production-rate, as calculated by the number of corpora lutea present in the ovaries, amounted to 9·95 per animal at each breeding period, these could be regarded as representing over 1600 ova. Ferrets ovulate only after insemination, and, according to Professor Robinson, not till after the spermatozoa have entered the caudal third of the oviduct. Other anatomical characteristics of the ferret, as well as the conveniently small size of its ovary for purposes of serial section, make it an excellent subject for this investigation. The genital apparatus of 165 animals, killed at intervals after insemination varying from 18 hours to 42 days, the usual period of gestation, yielded a considerable amount of material for detailed microscopical examination, the results of which have been tabulated by Professor ROBINSON.

[1] Edinburgh Medical Journal, xxvi., Nos. 3 and 4, March and April, 1921.

The prenatal death-rate of the extruded ova works out at 24·16 per cent., but since the animals were killed at various periods of gestation, and not at the end, the figure is not comparable with the horse figures. Professor ROBINSON suggests that some of the ova and zygotes which appeared normal in the first week or two of gestation would doubtless have shown signs of degeneration had the killing of the mothers been delayed. These and other considerations lead Professor ROBINSON to place the normal prenatal death-rate at not more than 39 per cent.; but, as he says, the exact percentage is unimportant. His main point is that in ferrets, as in horses, the prenatal death-rate in healthy animals in a normal environment is high and variable. In general support of the contention that this is probably true for other animals he adduces the observations of J. P. HILL on marsupials, of J. HAMMOND on swine, and of C. R. STOCKARD and G. N. PAPANICOLAOU on guinea-pigs, though he admits that the evidence is not conclusive.

Professor ROBINSON makes other interesting deductions, positive and negative, from his material. From breeding experiments alone, unless carried out on a very extensive scale, he considers that it would not be possible to say that any stallion, or probably any other male animal, was impotent. One thoroughbred stallion was infertile with 51 out of 52 mares with which he was mated, a second with 93 out of 103 mares, and one Clydesdale stallion with 96 out of 104 mares. The horse data give no help as to where, when, and how death takes place, but the evidence offered by the ferrets appears again to be confirmed by the work of HAMMOND on swine and rabbits, G. W. CORNER on swine, HILL on marsupials, and A. W. MEYER on intra-uterine absorption of ova, which show that the cause of prenatal death cannot in some cases be attributed to uterine disease. Professor ROBINSON finds that in ferrets extruded ova die in the peritoneal cavity, into which they have escaped; in the peri-ovarial sac, from which they have failed to escape into the oviduct; in the oviducts; and in the uterine cornua. They die when still ova, either lost in the peritoneal cavity or because they fail to unite with the spermatozoa present. As zygotes they die in the morula and in the blastula stage, after attachment to the decidua and after differentiation into embryo and appendages. The majority of the extruded ova become zygotes, and of these the majority which die in the prenatal period die after they have become attached to the decidua. How they die is more difficult to decide, but it is always apparently by an alteration of their structure, ending in disintegration. "The death is not due to inflammation or to micro-organismal attack, but apparently simply to an incapability to live and develop properly under conditions which are quite favourable to immediately adjacent zygotes."

After discussing and dismissing other possible factors, Professor ROBINSON concludes that the cause of prenatal death is the constitution of the gametes and zygotes, and further, that it is a structural peculiarity of the gametes which is the cause of sexual incompatibility. He goes still further. To him his material suggests that a large amount of the prenatal death which occurs in mammals is normal, that it is not dependent upon disease of the parents, detrimental environment, insufficient nutrition, or disease of the gametes, but is in a sense a side issue of the process which gives rise to the variations which appear so universally in all mammals and probably in all living beings. Again, if prenatal death is admitted to be constant and normal, Professor ROBINSON points out the obvious corollary that in some animals abortion also must be normal. In mammals which produce multiple young at birth, any dead zygotes are removed by absorption in all but the very latest stage, for obvious reasons. In animals which produce only one young after a long gestation period abortion immediately following death of the zygote, is an economical and necessary arrangement, as the uterine mucosa quickly regains a condition favourable to a new gestation. Thus the changes in the decidua usually regarded as degenerative, and as the possible cause of the death of the zygote may be the result thereof, and should in this case be regarded as regressive changes adapted to bring about as soon as possible a normal pro-œstral condition of the uterine mucosa. If Professor ROBINSON is right that a considerable number of abortions are not only normal but necessary, and adapted to prevent diminution of the birth-rate, his further contention that the condition of the uterine mucosa associated with them is not degenerative or diseased and that treatment directed thereto is unnecessary, if not detrimental, is justified. The discussion on sterility, its causation and treatment, reported in our present issue, would certainly appear to show that the practical clinical experience of obstetricians at least does not conflict with his experimental findings.

THE PROBLEM OF SLUM AREAS.

THE slum area of Brady-street, Bethnal Green, was the subject of a recent question in the House of Commons. The Minister of Health was asked whether the London County Council had presented to his Department a plan for dealing with the area, whether the plan had been approved or rejected, and when the Council had been informed of the decision. Sir ALFRED MOND replied to the effect that a local inquiry was held in June, 1920, into the scheme proposed by the London County Council; it was then found that adoption of the scheme involved a number of legal and administrative questions, of which settlement was necessary before a decision could be given upon the case in question. Action upon the scheme would in any case have to be deferred until further progress was made with provision of new houses. The numerous complications attendant, under existing conditions, upon any conveyancing of densely-populated property must inevitably tend to hamper the advancement of public health in this country; and it is made plain in the answer of the Minister of Health that even when slums have been acquired by local authorities for purposes of destruction, shortage of new houses still bars the way to demolition of property unfit for habitation. It may be true, as some would have us believe, that the slum-bred tenant speedily reduces any house he occupies to the level of his own personal squalor; but if any progress is to occur this fact constitutes no argument against the making of a steady effort to supply dwellings built and drained and lighted in such a way that the slum tenant may have at least the opportunity to prove the statement false.

Annotations.

"Ne quid nimis."

X RAY AND INFLUENZA SCARES.

THE Parisian popular press has recently promulgated two "scares," one having reference to the "danger" of living near a laboratory or clinic where X rays are employed, the other being an allegation to the effect that the country is on the eve of another influenza epidemic. The latter is the more serious suggestion of the two. A few cases of influenza have been reported at the ports of Brest, Cherbourg, and Lorient, and also inland, amongst troops stationed at Orleans, Saint-Estienne, Bourges, and Albi. In Paris at the end of April there had been no demand at the Pasteur Institute for anti-influenza vaccine. Most of the military cases have occurred among recruits who have recently joined their regiments. The symptoms are not so severe as those noticed during the great epidemic of 1918. The Minister of Hygiene, Mr. Lerédu, has, however, ordered the strict disinfection of public halls, schools, restaurants, cafés, kinemas, and theatres. The public has also been advised to avoid sudden changes of temperature, to isolate the sick, to observe great personal cleanliness, and to indulge abundantly in hot drinks. This latter welcome piece of advice will, of course, result in a renewed outcry against profiteering in rum. Hope is still entertained, however, that there will be no epidemic, and that the few cases mentioned are due to the recent sudden changes in the weather.

The apprehension lest proximity to X ray centres of employment should affect health, though it affects very few people, has led to almost as lengthy a controversy. Mr. Contremoulins, who won the Montyon prize for medicine and surgery and is laureate of the Institut, has sent a report to the Academy of Sciences on experiments of his own which indicate that it may be dangerous to live in a building where X rays are constantly employed. Journalists have thereupon invaded the laboratories of many known authorities, have obtained interviews, and have written long articles about X rays. At the Saint-Antoine Hospital, however, Dr. Iser-Solomon refused to consider the matter in a tragic light. He pointed out that to affect the health of persons living in the neighbourhood the X rays would have to pass through the walls of the building; the solidity of the walls and the distance must be considered. At the Saint-Antoine Hospital three X ray apparatuses are at work every morning and nowhere else in France is there so considerable a production of X rays. A ward full of patients is separated from the X ray theatre by nothing but a light partition wall, and on the floor above there are more patients. Neither the patients in their wards nor photographic films, many of which have been kept for a year near the X rays, have been affected. In any case, what danger there may be can be overcome by the use of lead to cut off the rays. To this and similar arguments, Mr. Contremoulins replied that the patients at the Saint-Antoine Hospital leave when cured, and he was concerned with the employment of X rays near private dwellings and their effect in the course of years. It is therefore a question not only of distance and the thickness of walls, but also of time.

PAPILLARY EPITHELIOMA OF THE RENAL PELVIS.

Dr. Edwin M. Miller and Dr. Robert H. Herbst,[1] of Chicago, reporting a case under their care, remark that primary papillary epithelioma of the renal pelvis is a rare tumour, only 54 cases having been recorded in the world's literature. The tumour is twice as common in males as in females, nearly half the cases occur in subjects between the ages of 50 and 60, about one-fifth between 40 and 50, and the same number between 60 and 70. The oldest case was in a woman, aged 86, and the youngest in a boy. As regards the ætiology, although it is possible that irritation from a calculus or chronic infection may be a predisposing factor, infection is mentioned in but three and calculus in only 10 of the 54 cases. The tumours may vary in character from multiple, small, isolated growths to a single large cauliflower-like mass, filling the renal pelvis and producing destruction of the renal parenchyma. They usually arise from the lining of the pelvis of the kidney, but sometimes originate in the terminal portion of the collecting tubules. Their histological structure resembles that of papillomata elsewhere in the urinary tract. Bleeding occurs readily, and the clots formed may block the outlet of the pelvis with consequent hydronephrosis, or cause varying degrees of obstruction as they pass down the urinary tract. The tumour may remain localised in the kidney or involve the lower urinary tract either by direct extension or by implantation. Of the 54 cases, 25 showed involvement of the ureter, and in 18 the tumour invaded the kidney, ureter, and bladder. The symptoms vary considerably with the size of the tumour and the associated pathology. Hæmaturia is the most constant manifestation. It is usually intermittent and may vary from a slight cloudiness of the urine to a severe hæmorrhage. Pain is inconstant, and ranges in degree from mild bladder irritation to severe colicky pains like those caused by ureteral stone. The condition may last for years in the absence of surgical treatment, but in the great majority of cases a relatively early termination takes place. As regards the diagnosis, the possibility of this condition should always be considered when intermittent hæmaturia occurs in adults in association with pain in the kidney region. It should be strongly suspected if the skiagrams show no stone and there are colicky pains along the ureter, diminution or absence of function of the affected kidney, and a palpable tumour in the loin. The diagnosis is confirmed by cystoscopy revealing a papilloma in the bladder or ureteral orifice, by the presence of otherwise unexplained epithelial cells in the urine, and by the pyelogram showing defect in the renal pelvis. The nature of the treatment depends on whether the bladder is involved or not. In the former cases complete removal of the kidney and ureter, followed by fulguration of the bladder implantations, is required; in the latter cases removal of the affected kidney and ureter is indicated.

THE MEASUREMENT OF ACTIVITY AND FATIGUE.

EFFICIENCY in industrial work is closely connected with activity and fatigue, which in their turn depend upon muscular and nervous energy. Considerable attention has recently been paid to this side of efficiency, but one of the difficulties experienced has been to obtain a direct measure of activity. Investigators mistrusting the introduction of subjective influences into any test used have been relying to a great extent upon records of output, concerning which the operatives have no knowledge that they may be used for the purposes of investigation; but a tendency is showing itself to have recourse to ergometric methods as originally carried out by Mosso. Recently we drew attention to the use in South African gold mines of specially devised ergometers to throw light upon the influence exerted by atmospheric conditions upon efficiency. A further investigation has now come under notice reported upon from France by Dr. H. Dausset and Dr. Boigey.[1] These workers made use of a universal registering goniometer capable of recording graphically the weights used, the number of movements made, their extent, and the total kilogrammes of work done. The activity of the deltoid, the biceps, and the extensor muscles of the hand were investigated on a number of subjects.

The curves obtained showed first a plateau during which the amplitude of the movements was constant, and then a decline during which the amplitude of each succeeding movement was less than that of its predecessor. So far the work simply corroborates that of Mosso. But a new point is introduced as the result of examining carefully a large number of curves. The observers found they could divide the curves into four main types: one in which the plateau was comparatively short followed by a long decline; a second in which the plateau was comparatively long followed by a short decline; a third with both plateau and decline short; and a fourth with a short plateau followed by an abrupt fall. The first two types may be obtained from similar amounts of work done. Thus 124 kilogrammeters of work was represented by a curve with 30 movements composing the plateau, and 115 in the decline which represented 58 per cent. of the work done. While another curve representing 114 kilogrammeters had 75 movements composing the plateau and only 28 in the decline, which represented 20 per cent. of the work done. Subjects who are described as strong and nervous (*au sens sportif du mot*) gave curves with short plateau and long decline. Strong and slightly nervous subjects gave curves with long plateau and short decline. The third type was found associated with an inferior amount of work done, and to be obtained from invalids and nervous subjects, while the fourth type represented asthenia and was obtained from feeble and slightly nervous persons.

[1] Sur l'utilité des Courbes de Fatigue pour le control de l'Entrainement en education Physique," by Drs. H. Dausset and Boigey Paris Médical, April 16th, 1921.

The plateau is claimed to represent the period of activity before the onset of fatigue, and the decline the definite appearance of impaired nervous activity. The relation of one to the other is proposed as a measure of the capacity of the individual to resist fatigue. "This evaluation should lead to a precise classification of subjects according to their mode of resisting fatigue, the part played by the nervous and muscular elements being variable." The authors suggest that fatigue curves of this kind, taken at regular intervals, might provide a control during athletic training; "a control much more precise than the criteria actually in use. It should permit the physical exercises of patients to be graduated at will; by these means the amount of nervous exhaustion caused by excessive work, by violent exercise, or by overtraining could be valued." Great interest would attach to measurements made in this way on industrial workers, compared subsequently with records of output. In the absence of any direct test of fatigue we hope that attention will be given to following up the field of investigation opened out by this interesting research.

THE SPECIFICITY OF THE SYPHILITIC ORGANISM IN GENERAL PARALYSIS.

WHILE the debate on the biology of the *Treponema pallidum* in common syphilitic affections and general paralysis continues with undiminished vigour, a young and hitherto unknown Italian scientist, Dr. Sanguineti,[1] has brought to light in Paris a thesis of his which attempts some explanation of this problem and may be considered a new interpretation of the ætiological and clinical aspects of progressive paralysis. It is well known that Levaditi and Marie maintain that ordinary syphilis is due to a dermotropic treponema, while progressive paralysis is caused by a neurotropic treponema, and they back up their opinion with the following biological variations met with in both, viz.:—

(1) That the neurotropic treponema has a period of incubation much longer; (2) that in rabbits the dermotropic treponema when inoculated into the scrotum gives rise to a hard sore, whereas the neurotropic produces a diffuse papulo-squamous lesion; (3) that the neurotropic has a greater epithelial and perivascular affinity, while the dermatropic has an *endovascular* affinity and a marked sclerosing action; (4) that the lesion caused by the neurotropic in rabbits develops slowly and recovers spontaneously; and (5) that the animals rendered refractory to either virus are not so towards the other.

These conceptions receive some clinical confirmation, for no one who has had the opportunity of observing a large number of cases will deny the existence of two well-marked forms of syphilis, one developing with cutaneous mucous and grave visceral lesions, the other affecting slowly the nervous system. On the other hand, the unicists, led by Sicard, still hold that the evidence put forward by Levaditi and Marie is not completely proved as yet, since neurotropism might well be interpreted as a special attribute acquired by the treponema during its long sojourn in the nervous system, and similarly other biological peculiarities might well have been acquired by either virus during a series of years in the various tissues in which it was lodged. Now Sanguineti has made a study of a hundred general paralytics, inquiring especially into the condition of the consort and descendants, and hence the relationship with the two different forms of syphilis which he thus describes; a latent syphilis which after the primary infecting sore is free from specific manifestations, and a florid syphilis which gives rise to the well-known secondary symptomatology. (It will be gathered that what follows is the substance of Sanguineti's thesis.) In the first case the infection is due to a neurotropic treponema which from the commencement will fix itself in the brain; in the second case it is the generic treponema which is concerned and ordinary syphilis results. Neurotropic syphilis gives rise to a paralysis which may break out 10–15 years after infection, and at the onset reveals itself in phenomena of psychic and somatic exaltation, leads to late dementia, leaves intact for a long time the general physical condition, does not infect the consort, gives a negative Wassermann, and induces towards an offspring of irregular development but of marked precocity. The other, ordinary syphilis, causes, on the other hand, a general progressive paralysis with very different characteristics, in that it begins 2 to 3, or 25–30 years after infection, leads to rapid dementia with bodily and psychic depression, infects the consort, gives a positive Wassermann and induces towards an offspring late development, and signs of hereditary syphilis. The first variety constitutes 74 per cent. of all cases of progressive general paralysis, the second 22 per cent. Sanguineti, however, admits the existence of mixed forms (4 per cent.) in which elements of one or the other are found when the soil offered by the patient allows the treponema to fix itself early in the nervous system after having given rise to well-marked specific manifestations. From an anatomico-pathological aspect he has noticed that in the first variety the arteries remain soft and normal, so that the mental symptoms must be explained by the direct action of the neurotropic germs on the nerve cells, while in the second type the arteries are sclerotic, so that these phenomena are the result of vascular and nutritive changes. The treatment of both forms by specific methods is devoid of result—in the former by the impossibility of reintegration of the elements invaded by the treponema; in the second on account of the extent of the arterial disorganisation. He has hopes, however, of a future serological therapy not yet realisable.

"BOTULISM" FROM CHEESE.

IN the March number of the *Journal of Infectious Diseases*, published at Chicago, there is an interesting contribution on the subject of "Botulism from Cheese" by Miss Mary Nevin, of the Research Laboratories of the New York State Department of Health, giving some account of an outbreak of botulism which occurred in 1914, attributed to the eating of "home-made cottage cheese." Three persons who had eaten the cheese died, and samples were sent to the State Research Laboratories for examination. The nature of the fatal illness was not at first diagnosed, but ultimately it was recognised that the clinical picture in these patients corresponded with that described by Ostertag, van Emenengen, and others. The symptoms included paralysis of the muscles of deglutition, suffusion of the face, ptosis, total dilatation and failure of the pupils to react to light, paralysis of the muscles of the throat, with difficulty of speech. The cheese was bacteriologically examined, and *B. botulinus* was isolated from the sample. Miss Nevin claims that this is the first time that this bacillus has been identified in cheese. The early investigators of botulism thought that the toxin was produced by the bacillus only in the presence of meat protein. Since then, however, it has been shown that the toxin has been produced in association with vegetable protein. It is, therefore, apparent that meat protein is not necessary to the growth and consequent production of toxin by *B. botulinus*, and that cheese can serve as a medium.

---

[1] La Riforma Medica, April 9th, 1921.

RUPTURE OF ANEURYSM OF THE SPLENIC ARTERY DURING PARACENTESIS ABDOMINIS.

Dr. J. Garland has recently reported[1] a very rare fatal complication of paracentesis abdominis. A man, aged 52 years, a granite polisher, was admitted to the Massachusetts General Hospital on August 6th, 1920, complaining of dyspnœa on exertion and œdema. There was a history of gonorrhœa at 29, but syphilis was denied. About four months ago his feet became swollen at night and he stopped work for a week. The abdomen was slightly distended. Although the swelling was not much reduced he returned to work, but after half a day's work the swelling greatly increased and he became dyspnœic and returned to bed. On examination he was well nourished and of a good colour. The left pupil was larger than the right, but both pupils reacted normally. There was a small right retinal hæmorrhage and a few fine râles were heard at the bases of the lungs. The cardiac impulse was in the fourth interspace 13 cm. to the left of the middle line. The action was slightly rapid and the aortic second sound was accentuated. There was a systolic murmur at the apex and a diastolic over the left fourth interspace at the sternal border. The pulses were equal and synchronous and of high volume and tension. The artery walls were palpable. The blood pressure was 210, systolic; 125, diastolic. The abdomen was distended and tympanitic with a definite fluid wave and shifting dullness. The scrotum and feet were œdematous and a fine tremor of arms and hands was present. The knee-jerks were normal. The temperature varied from 98° to 103° F. The urine contained a trace of albumin, white and red blood corpuscles, and rare granular casts. On two examinations occult blood was found in the stools. The Wassermann reaction was positive. Radiographic examination showed definite change in the heart shadow, especially to the left. Digipuratum was given and on August 16th paracentesis abdominis was performed; 5500 c.cm. of slightly cloudy, straw-coloured fluid were withdrawn. On the 19th the temperature and leucocyte count were elevated and the patient was weaker. Both bases were dull, but the œdema was gradually disappearing. On August 20th paracentesis was performed at 9 A.M., the trocar being inserted in the mid-line about midway between the umbilicus and symphysis. After 1200 c.cm. slightly cloudy reddish fluid had been withdrawn the flow stopped. As there still seemed to be fluid in the abdomen the trochar was again inserted about half an inch lower. Immediately the patient felt a sharp pain in the abdomen and the needle was withdrawn. Slight bleeding from the puncture followed, and the patient became pale and showed signs of collapse, with a weak, thready pulse and cold extremities. Respiration was periodic and gasping. Intravenous injection of saline solution was attempted, but the veins were too collapsed to be entered. Death occurred at 12.30 P.M. At the necropsy 3000 c.cm. of thin bloody fluid and a large amount of clot, weighing about 1100 g., were found in the peritoneum. The splenic artery was calcareous and showed an aneurysm about 3 cm. in diameter, with a crevice about 4 mm. long in a fibro-calcareous area. The sac contained a small amount of blood and clot. The case is interesting on account of the rarity of the lesion and the dramatic ending, the rupture occurring during the simple procedure of paracentesis abdominis. The reason for the rupture at this moment can only be conjectured. The excitement of moving the patient and performing the operation might have increased the blood pressure to the bursting-point of the aneurysm, or the withdrawal of the fluid in the peritoneum may have diminished the pressure of the structures surrounding the aneurysm. Direct trauma from the trocar was shown at the necropsy to have been impossible. In over 4100 necropsies at the Massachusetts General Hospital aneurysm of the splenic artery was found three times.

"IMAGINATION, COÖPERATION, AND ENTHUSIASM."

ON May 5th the Savoy Hotel, London, washed its dirty linen in public, and far from being an unsightly, evil-smelling, or otherwise unseemly procedure it was a revelation of the possibilities of laundry-work. A V-shaped building, of which one arm is devoted to work and the other to welfare, presents many interesting features. We could spend much time describing the processes of marking (by sewing on labels, not by a red cotton spider) and sorting; the drums which wash by rotating through soapsuds; the perforated ringers, which do not twist; and the drying and ironing machines. But we can comment here only on two details. Those who are specially interested in the spread of infection will rejoice to hear that the handkerchiefs are kept separate throughout, and, when washed apparently clean, are boiled more than once; while to the wearers of the double collar we would speak of a moulding machine which gives a round edge to its bend, leaving room for the tie to slip easily. But we are more concerned with the welfare of the cheerful-looking men and girls who feed the machines, fold, and sort the linen into rubber-wheeled trollies, and of the specially skilled hands who manipulate the electric irons. The atmosphere is fresh and cool throughout the building; a representative of the Industrial Fatigue Research Board, who is investigating conditions in the laundry trade, is now making interesting comparative observations in this laundry. Each employee is weighed and medically examined on engagement, and his or her condition card-indexed. A weekly medical inspection is then carried out. The triangular welfare room and surgery combined has doors at each angle of its base, so that the staff can file past the doctor, with bare chests and arms, with the least possible delay, and dermatitis or scabies can thus easily be detected. Those who wish to consult the doctor, or who look ill, are given a ticket and return later for a more detailed examination. Dental cases are referred to hospitals or clinics. A full-time welfare worker, who has had nursing experience, is in charge of this welfare room, and provides first-aid treatment and the medical officer proposes shortly to start a series of lectures or informal talks on hygiene to the workers. Each girl, having been passed by the doctor, is given a steam-heated ventilated metal locker where her out-door garments can dry if necessary, and where she keeps the hand towel provided for her individual use. Ample lavatory accommodation is available. Wash troughs with many separate jets replace the ordinary basin and plug. Two bath-rooms are in constant use by the staff in rotation during working hours, so that every employee can have a bath a week. The working hours are 8 to 6, with an hour off for dinner at 12, and 10 minutes' break at 10 A.M. and at 3 P.M. Dinner is provided at a low price in a spacious mess-room, with polished floor available for dancing; it seats 150 at small tables, and separate chairs with backs are provided. This canteen is also open for the supply of tea and coffee half an hour before work starts in the morning. The employees much appreciate this arrangement, for difficulties are frequently associated with the domestic facilities of workers for obtaining food early in the morning. A general committee of employees, from which even forewomen are excluded, elects appropriate subcommittees to arrange the bill of fare for the meals and occasional entertainments. A rest-room, lending library, and tiled kitchen with steam and gas apparatus, complete this part of the building. The flower and fruit garden lies between the two arms of the V and is well planned; a vegetable garden adjoins. A week's holiday on full pay is granted to each employee who has worked for a year, increasing by a day a year to a fortnight.

---

[1] Boston Medical and Surgical Journal, April 14th.

It is the human side of the undertaking that is most striking, and the pleasant impression is given that the human element is regarded as the most important part of the machinery of this very complex factory, which, by the way, is open to inspection by appointment. Regular meetings between the manager and the staff take place, when valuable hints as to possible improvements have been offered by the latter. This arrangement ensures also that grievances will be ventilated and discussed. Laundry-work has hitherto been considered one of the most backward and difficult trades to organise on a healthy basis, but this appears to be good pioneer work. When the economic aspect of this excellent scheme of preventive medicine is considered the debit side of the account, the money actually expended, which is easy to reckon, may at first sight seem to outbalance the credit side, which is less easy to estimate and is not so immediately obvious. But when decrease in labour turnover, and in lost time, increase in quality and quantity of work, and that indefinable though invaluable asset, a contented personnel, come to be reckoned up, the debit side sinks into the background, and the scheme is found to be based on true economy. Even on the present scale of charges it is hoped that a laundry run on these lines may be made remunerative. It is noteworthy that the personal laundry of the hotel staff is done here as well as that of the visitors. But clean healthy laundries are at least as desirable as clean milk, and for both an adequate price will have to be paid. Meanwhile, it would be difficult to find words more appropriate to describe the impression created by this most recent addition to our model factories than those of "Imagination, Coöperation, and Enthusiasm" adopted by the manager as its watchword.

THE CYCLE OF CHOLESTEROL IN THE ORGANISM.

ACCORDING to A. Chauffard, G. Laroche, and A. Grigaut,[1] there are three factors which determine the metabolism of cholesterol, the food, certain endocrine glands, and the liver. The influence of food is but temporary, and any increase of cholesterol in the blood rapidly disappears. The most important endocrine factors are the cortex of the adrenals and the corpora lutea. The latter contain much cholesterol, but are only active at certain periods. The cells of the adrenal cortex are the chief factories of cholesterol in the organism. The adrenals surpass all other organs in their cholesterol-content, even the nervous system itself. In the adrenals of individuals killed suddenly cholesterol forms 42–54 per mille of the fresh gland; in those who die of disease there is only 20 per mille. Cholesterol appears to exist in two forms in the adrenals; part is "fixed" and forms an integral part of the construction of the cells, while the larger part is mobile. The former or "organ-cholesterol" appears to be common to all organs and amounts to about 2·5 per cent. This seems specially evident in the fœtus. During the first five months the adrenals contain about the same amount as the liver and kidneys, corresponding to the amount of organ-cholesterol in the adult. During development the amount of cholesterol in these organs does not increase, while the amount in the adrenals from the sixth month (at the seventh month it is 8·16 per cent.) greatly increases and at birth reaches 36 per cent. At the sixth to the seventh month the cells of the cortex take on their cholesterol-forming function, probably corresponding to the greater demands of the growing organism for cholesterol. The authors give their reasons for not regarding the adrenals as merely storage organs for cholesterol. The increase of this substance in the cortical cells is associated with other indications of their cell activity. The liver and bile play an important part in the cholesterol cycle. The bile by the amount of its cholesterol gives an indication of the activity of the hepatic cells which secreted it, and on the whole the amount of cholesterol in the bile runs fairly parallel with the amount present in the blood. Ligature of the bile-duct increases the amount of cholesterol in the blood. During gestation the fœtus seems to receive some cholesterol from the mother.

THE MEDICAL AND DENTAL REGISTERS.

THE *Medical Register* for 1921 contains 41,761 names, being an increase of 251 on the number recorded the previous year. 1457 names were added during the year on registration—457 in England, 393 in Scotland, and 264 in Ireland; the last figure being the highest recorded and double the entries of 20 years ago, whereas the figures for Scotland and England have declined in the same period. 333 names have been added to the separate Colonial List, to which attention is now called by painting blue the edges of the leaves. From year to year it becomes more inopportune to place these names at the end of a large volume, where they may readily be overlooked, when the privileges and duties attached to registration are precisely the same in whatever part of the Register the name is entered. Ten new names appear on the Foreign List, the degree-granting university being in one instance each Florence, Brussels, Louvain, Bologna, Palermo, Turin, and in four instances Ghent. Reciprocity has ceased with Belgium, and no further registrations will be accepted without examination. It would add to the helpfulness and interest of the Register if the numbers of men and women respectively were severally noted.

The *Dental Register* for 1921 contains 5610 names, being an increase of 155 on the number recorded the previous year, a matter for congratulation. Eighteen new names appear on the Colonial List and 5 on the Foreign List, the professional qualifications of the last-named having been obtained at Kharkoff (2), Petrograd (2), and Novorossiisk. The number of British registrations occurring in 1920 was the same as in 1917 and 1914.

The Medical and Dental Students Register contains the names of 2531 medical students and 560 dental students who have passed their entrance examinations and entered for professional study.

COLSTON UNIVERSITY RESEARCH SOCIETY, BRISTOL. This Society, formerly known as the University of Bristol Colston Society, collects funds annually for the furtherance of research in the University of Bristol, and is believed to be the only society of its kind in Britain. Last year, under the presidency of the Bishop of Bristol, £406 was collected. This year's President is Alderman Frank Sheppard, and the guest of the evening at the forthcoming annual dinner will be Sir W. H. Bragg. The Society has recently published a brief summary of work done during the past three years. Under the heading of chemistry there is a brief reference to the work of Dr. M. Nierenstein on tannins. In the departments of anatomy and physiology Professors E. Fawcett and G. A. Buckmaster are pursuing their personal researches, the former on the morphology of the cranium, and the latter on the transport of carbon dioxide. Professor Buckmaster and Dr. Hickman are also engaged on the production of apparatus for simplified electro-cardiography and the recording of body movements. Mr. A. L. Flemming is investigating the action of surgical anæsthesia on respiration. From the department of pathology Professor Walker Hall announces progress in investigation into the relation between nutrients and the life-history of pathogenic bacteria. The department of medicine reports researches by Professor F. H. Edgeworth into the development of the laryngeal muscles; also work by Dr. Carey Coombs on the ætiology of rheumatic heart disease (an account of which appeared in THE LANCET, 1920, ii., 220), and work by Dr. Coombs, with Dr. C. E. K. Herapath, on the intrinsic anatomy of the human auricles. Alderman Sheppard, in his appeal for funds, says that at least £1000 a year are needed to maintain pre-war activities.

[1] Ann. de Méd., 8, 1920.

face, ptosis, total dilatation and failure of the pupils to react to light, paralysis of the muscles of the throat, with difficulty of speech. The cheese was bacteriologically examined, and *B. botulinus* was isolated from the sample. Miss Nevin claims that this is the first time that this bacillus has been identified in cheese. The early investigators of botulism thought that the toxin was produced by the bacillus only in the presence of meat protein. Since then, however, it has been shown that the toxin has been produced in association with vegetable protein. It is, therefore, apparent that meat protein is not necessary to the growth and consequent production of toxin by *B. botulinus*, and that cheese can serve as a medium.

RUPTURE OF ANEURYSM OF THE SPLENIC ARTERY DURING PARACENTESIS ABDOMINIS.

Dr. J. Garland has recently reported[1] a very rare fatal complication of paracentesis abdominis. A man, aged 52 years, a granite polisher, was admitted to the Massachusetts General Hospital on August 6th, 1920, complaining of dyspnœa on exertion and œdema. There was a history of gonorrhœa at 29, but syphilis was denied. About four months ago his feet became swollen at night and he stopped work for a week. The abdomen was slightly distended. Although the swelling was not much reduced he returned to work, but after half a day's work the swelling greatly increased and he became dyspnœic and returned to bed. On examination he was well nourished and of a good colour. The left pupil was larger than the right, but both pupils reacted normally. There was a small right retinal hæmorrhage and a few fine râles were heard at the bases of the lungs. The cardiac impulse was in the fourth interspace 13 cm. to the left of the middle line. The action was slightly rapid and the aortic second sound was accentuated. There was a systolic murmur at the apex and a diastolic over the left fourth interspace at the sternal border. The pulses were equal and synchronous and of high volume and tension. The artery walls were palpable. The blood pressure was 210, systolic; 125, diastolic. The abdomen was distended and tympanitic with a definite fluid wave and shifting dullness. The scrotum and feet were œdematous and a fine tremor of arms and hands was present. The knee-jerks were normal. The temperature varied from 98° to 103° F. The urine contained a trace of albumin, white and red blood corpuscles, and rare granular casts. On two examinations occult blood was found in the stools. The Wassermann reaction was positive. Radiographic examination showed definite change in the heart shadow, especially to the left. Digipuratum was given and on August 16th paracentesis abdominis was performed; 5500 c.cm. of slightly cloudy, straw-coloured fluid were withdrawn. On the 19th the temperature and leucocyte count were elevated and the patient was weaker. Both bases were dull, but the œdema was gradually disappearing. On August 20th paracentesis was performed at 9 A.M., the trocar being inserted in the mid-line about midway between the umbilicus and symphysis. After 1200 c.cm. slightly cloudy reddish fluid had been withdrawn the flow stopped. As there still seemed to be fluid in the abdomen the trochar was again inserted about half an inch lower. Immediately the patient felt a sharp pain in the abdomen and the needle was withdrawn. Slight bleeding from the puncture followed, and the patient became pale and showed signs of collapse, with a weak, thready pulse and cold extremities. Respiration was periodic and gasping. Intravenous injection of saline solution was attempted, but the veins were too collapsed to be entered. Death occurred at 12.30 P.M. At the necropsy 3000 c.cm. of thin bloody fluid and a large amount of clot, weighing about 1100 g., were found in the peritoneum. The splenic artery was calcareous and showed an aneurysm about 3 cm. in diameter, with a crevice about 4 mm. long in a fibro-calcareous area. The sac contained a small amount of blood and clot. The case is interesting on account of the rarity of the lesion and the dramatic ending, the rupture occurring during the simple procedure of paracentesis abdominis. The reason for the rupture at this moment can only be conjectured. The excitement of moving the patient and performing the operation might have increased the blood pressure to the bursting-point of the aneurysm, or the withdrawal of the fluid in the peritoneum may have diminished the pressure of the structures surrounding the aneurysm. Direct trauma from the trocar was shown at the necropsy to have been impossible. In over 4100 necropsies at the Massachusetts General Hospital aneurysm of the splenic artery was found three times.

"IMAGINATION, COÖPERATION, AND ENTHUSIASM."

ON May 5th the Savoy Hotel, London, washed its dirty linen in public, and far from being an unsightly, evil-smelling, or otherwise unseemly procedure it was a revelation of the possibilities of laundry-work. A V-shaped building, of which one arm is devoted to work and the other to welfare, presents many interesting features. We could spend much time describing the processes of marking (by sewing on labels, not by a red cotton spider) and sorting; the drums which wash by rotating through soapsuds; the perforated ringers, which do not twist; and the drying and ironing machines. But we can comment here only on two details. Those who are specially interested in the spread of infection will rejoice to hear that the handkerchiefs are kept separate throughout, and, when washed apparently clean, are boiled more than once; while to the wearers of the double collar we would speak of a moulding machine which gives a round edge to its bend, leaving room for the tie to slip easily. But we are more concerned with the welfare of the cheerful-looking men and girls who feed the machines, fold, and sort the linen into rubber-wheeled trollies, and of the specially skilled hands who manipulate the electric irons. The atmosphere is fresh and cool throughout the building; a representative of the Industrial Fatigue Research Board, who is investigating conditions in the laundry trade, is now making interesting comparative observations in this laundry. Each employee is weighed and medically examined on engagement, and his or her condition card-indexed. A weekly medical inspection is then carried out. The triangular welfare room and surgery combined has doors at each angle of its base, so that the staff can file past the doctor, with bare chests and arms, with the least possible delay, and dermatitis or scabies can thus easily be detected. Those who wish to consult the doctor, or who look ill, are given a ticket and return later for a more detailed examination. Dental cases are referred to hospitals or clinics. A full-time welfare worker, who has had nursing experience, is in charge of this welfare room, and provides first-aid treatment and the medical officer proposes shortly to start a series of lectures or informal talks on hygiene to the workers. Each girl, having been passed by the doctor, is given a steam-heated ventilated metal locker where her out-door garments can dry if necessary, and where she keeps the hand towel provided for her individual use. Ample lavatory accommodation is available. Wash troughs with many separate jets replace the ordinary basin and plug. Two bath-rooms are in constant use by the staff in rotation during working hours, so that every employee can have a bath a week. The working hours are 8 to 6, with an hour off for dinner at 12, and 10 minutes' break at 10 A.M. and at 3 P.M. Dinner is provided at a low price in a spacious mess-room, with polished floor available for dancing; it seats 150 at small tables, and separate chairs with backs are provided. This canteen is also open for the supply of tea and coffee half an hour before work starts in the morning. The employees much appreciate this arrangement, for difficulties are frequently associated with the domestic facilities of workers for obtaining food early in the morning. A general committee of employees, from which even forewomen are excluded, elects appropriate subcommittees to arrange the bill of fare for the meals and occasional entertainments. A rest-room, lending library, and tiled kitchen with steam and gas apparatus, complete this part of the building. The flower and fruit garden lies between the two arms of the V and is well planned; a vegetable garden adjoins. A week's holiday on full pay is granted to each employee who has worked for a year, increasing by a day a year to a fortnight.

Public Health Services.

Hospitals and Insured Patients.

A RECENT meeting between members of the British Hospitals Association and representatives of the principal Approved Societies discussed the possibility of providing institutional treatment for members of these societies in return for contributions on an agreed percentage basis. The arrangement would involve some measure of priority being given to members requiring in-patient treatment over other cases of like urgency. If the hospital committees generally should prove inclined to grant this preference, the two parties will meet again for the purpose of drafting a definite scheme. In the meantime we note with satisfaction that at its annual conference, held early this week, the National Deposit Friendly Society decided to allocate £127,000, namely one-third of surplus of £381,000 for the treatment of its members in hospitals.

Paying Patients at Poor-law Hospitals.

An important deputation from the British Medical Association was received on April 26th by Sir Alfred Mond and some of the principal officers of the Ministry of Health, when Sir Clifford Allbutt and Dr. R. A. Bolam emphasised the desire of the Association to work in harmony with the Ministry. Mr. N. Bishop Harman, as chairman of the Hospitals Committee, then laid before the Minister three points which the Association regarded as essential to the utilisation of Poor-law hospitals for civil needs:—

1. The local medical profession of the districts concerned should be consulted with regard to any scheme which it was proposed to bring into operation.
2. Patients should only be accepted, as a general rule, on the recommendation of a private practitioner.
3. Private practitioners should have the right of entry so that patients might continue to be attended within the institution by the practitioner of their choice.

In reply the Minister of Health admitted that the whole position of the voluntary hospitals was one of great difficulty owing to their foundation in the past upon the generosity of private individuals and the generosity of the medical profession. Our voluntary hospitals had been equal, if not superior, to any run on municipal or State lines in other countries. There was much to be said for the close coöperation of voluntary effort, and he did not think anybody would like to see the voluntary system disappear. He felt hopeful that we were not always to remain in the present financial difficulties. Many people of means who found it impossible to go to nursing homes and inconvenient to be nursed at home, were looking for some institution which would enable them to get reasonable nursing and medical attendance on cheaper terms. Something was now being done in our general hospitals, following the lead of St. Thomas's. He hoped for further developments in this direction. In continental countries people did not hesitate to go into a large municipal hospital. People here would have to get rid of prejudice a little and make use of institutions. The whole question of Poor-law administration was tied up with the legal position of boards of guardians which could not be altered except by legislation. The Ministry had made an endeavour at Bradford to put into practice the principle of consultation with professional men, and he thought that would prove to be a valuable line. But boards of guardians could not be compelled: they could only be advised.

The suggestion of only allowing people to use the infirmary on the recommendation of a general practitioner had, Sir Alfred Mond agreed, many advantages, but he also saw difficulties. Suppose a patient wanted to go there and the doctor attending refused to allow him to go. The patient then might change his doctor and find one who would send him. That was a possible contingency. Or a man might insist on going and create difficulty. The doctor had some knowledge of the patient's financial standing, and would be in a position to judge whether he ought to go to the infirmary or not. But that might be putting on the doctor a line of examination suitable only to a chartered accountant. He did not wish to create opportunities of friction between the doctor and his patient.

Sir Alfred Mond concluded with a promise to go into all these matters with a view to being as helpful and sympathetic as the circumscribed powers which he possessed would permit, and he suggested another meeting for further discussion.

Workmen's Contributory Hospital Scheme.

A contributory scheme has been working well since the beginning of the year in connexion with the Norfolk and Norwich Hospital. This hospital, which serves a large part of the county, requires something like £250 a week to make its income and expenditure account balance. Each parish in the county is now being asked to accept its proper share of responsibility, which amounts to about 2*s*. 3*d*. per head. As patients, on the whole, are willing to contribute towards the cost of their maintenance and treatment, there is a good prospect of a solution of the question of voluntary hospital finance in Norfolk without any levy on the rates.

Women Practitioners and a Restricted Panel.

An important side issue affecting the new allocation scheme came before the London Insurance Committee on April 28th. Four women practitioners on the London medical list prefer not to undertake the treatment of men patients, and the insurance committee admits that it is not unreasonable for them to decline to do so. But under the terms of the 1921 contract any practitioner who is relieved by the insurance committee of the liability to have insured persons assigned to him surrenders 7½ per cent. of his share in the practitioner's fund. It may be doubted whether Section 5 of the Distribution Scheme was intended to have this construction placed upon it. While there are women who may prefer to have a mixed practice and would regard any restriction as a tacit admission of sex disqualification, there are others whose natural bent is towards children and adults of their own sex. Should the latter be willing to have any insured women assigned to them, they are not restricting their lists capriciously. Their bent may well be in the public interest; the question merits a solution on public grounds, and, in the meantime, it is hardly fair to mulct them in a substantial part of their income. They would be quite entitled to retaliate by choosing their own panel entirely and refusing to have *any* patients assigned to them. We cannot avoid the impression that the London Insurance Committee has misinterpreted the spirit of the regulations, if not their letter.

Medical Records.

The London Panel Committee recently resolved that the present medical records are neither advantageous to the medical service nor beneficial to the community, and that it is desirable they should be discontinued forthwith. No concrete suggestion was offered for any alternative form of record. At its meeting on April 28th the London Insurance Committee, without expressing any opinion on the present form of record, recommended that provision should be made in the records for all matters likely to be of value in connexion with the case. That is, of course, the crux. What is likely to be of value? One illustration may serve. Dr. Stevenson noticed some years ago that gastric ulcer was disappearing from the certificates as a cause of death in young women. Was this due (as we believe) to a change in the interpretation of hæmatemesis or to an actual alteration in the incidence of gastric disease? Hospital records deal with too selected a population to decide the point. There is nothing left but the records of panel practice.

Range of Medical Service.

The Wigan Insurance Committee has circularised the insurance committees throughout the country pointing out the cumbersome and expensive procedure necessary to decide whether or not an operation comes within the scope of medical benefit, and suggesting that every kind of medical treatment should be made available to insured persons under the provisions of the National Insurance Acts. The London Insurance Committee, concurring in this view, has passed on the recommendation to the Minister of Health. Formal resolutions such as these, useless though they may appear, will strengthen the hands of those who are determined to offer a complete medical service to insured persons.

In Wiltshire county during the first quarter of 1921 some 12,500 persons applied to make their own arrangements for medical treatment—namely, 12,311 with the G.W.R. Medical Fund Society, 103 with the R.A.M.C., 97 with the Salisbury Infirmary, and 6 on personal grounds.

UNIVERSITY OF BRISTOL APPEAL:
THE CLAIMS OF THE MEDICAL SCHOOL.

(FROM A CORRESPONDENT.)

IN an address to the Bristol Medical School some years ago the late Sir William Osler remarked that some universities had both money and men; others had plenty of money but no men; others, again, had the men but not the money. Bristol has never failed to produce the men, so far as medicine is concerned. If we look back at the brief history of the University movement in Bristol we find that as early as 1814 there were lectures on "Physiology, Pathology, and the Practice of Medicine" by Dr. J. C. Prichard. To these other lectures were added, and in 1832 the Bristol Medical School issued a prospectus, in effect an apologia for the establishment of a school of medicine in the provinces. A year before this the Bristol Medical Library had been formed. In 1874 the foundation of University College, Bristol, was publicly proposed by the late Dr. John Percival, Bishop of Hereford (at that time headmaster of Clifton College), supported by Dr. Temple, Dr. Jowett, Professor Freeman, and others, and in 1876 its first session opened in temporary premises. In 1893 the medical school became affiliated to University College, and was, with the medical library, housed in the permanent premises of the College, the local medical profession contributing more than half the cost of the buildings.

Since that time many considerable additions have been made to these premises, thanks to the generosity of the Wills and Fry families in particular. At the present time a magnificent block of buildings, giving the University (as it became by Royal Charter in 1909) a fine frontage in a main thoroughfare, is being built by the brothers George and Henry Wills in memory of their father, himself first Chancellor of the University, at a cost of £500,000. Not only so, but the same donors have given to the University the Royal Fort House and its gardens, with a site and funds for a new department of physics; the Victoria Rooms, a large public hall, for conversion into a students' union; and several other houses for halls of residence.

Now, the Faculty of Medicine played so honourable and active a part in laying the foundation on which this splendid superstructure is being reared, that its claims to consideration ought to be met in the near future. The distinguished men in charge of the departments of anatomy and physiology have adequate premises, equipment, and assistance. Those in charge of the final subjects are, however, less fortunate. They have no real departments at all, clinical teaching being carried on in institutions separate from the University where they deliver their systematic lectures. What is wanted is a constructive policy to unify these institutions with the University in such a manner as to ensure that any future disposition of existing or new buildings shall make adequate provision for the systematic teaching of medicine in every form. This is a difficult matter, but there is reason to believe that the strenuous efforts made in this direction during the past few years may ultimately be crowned with success. Moreover, the Vice-Chancellor has stated plainly that an early charge on the funds raised by the appeal will be the endowment of professorships in the Faculty of Medicine. If these expectations are realised, the Bristol Medical School should become a leading provincial school of England.

CONTROL OF VENEREAL DISEASE.

Occupation and Venereal Disease.

THIS very difficult question is raised in the report of the medical officer of health for the City of London, presented to the Sanitary Committee on Feb. 22nd last. In May, 1919, Dr. W. J. Howarth gave to his committee particulars of the occupations of 104 patients, and suggested that the matter should be brought to the notice of the Local Government Board with a recommendation that it should be made illegal for persons suffering from venereal diseases to be engaged in certain specific occupations.

In the recent report Dr. Howarth submits a tabular statement showing the occupations of over 1100 patients. The list includes persons engaged in the preparation and handling of food, hair-dressers, domestic servants, &c. In the case of the ordinary notifiable infectious diseases, interference with the occupation of the patient comes as a matter of course, though special difficulties arise in the case of diphtheria or enteric fever "carriers." The General Order of December, 1912, which made tuberculosis notifiable, contains in Article XVI. a special proviso according to which the person notified is not to be subjected to "any restriction, prohibition, or disability affecting himself or his employment, occupation, or means of livelihood on the ground of his suffering from tuberculosis." The object of this proviso was, no doubt, partly humane—to prevent the notified person from being regarded as a pariah, and partly due to the fact that such restrictions might lead to the concealment of the disease and a failure to secure adequate treatment in its early and more hopeful stages. Before the General Order came into force we believe it was customary for sanitary authorities operating under local Acts to exercise some interference with respect to persons suffering from "open" pulmonary tuberculosis who were engaged in occupations such as dairying, baking, or cooking. Objections also inevitably came from fellow-workers, in the case of indoor occupations, to working in contact with a person known to be suffering from an infectious stage of pulmonary tuberculosis. It therefore comes about that Article XVI., whatever may have been the intention of its framers, has not been effective in enabling the consumptive to carry on an occupation for which he is physically fitted, but from which he should be excluded on public health grounds. Fortunately, in the case of the consumptive it is usually desirable in his own interest that he should engage in an occupation of an outdoor character which renders him no danger to his fellows, and the need for a change of work can generally be suggested to him for the sake of his own health.

When we turn to the much more difficult question of the occupation of persons suffering from venereal diseases, we feel that in the first instance we want a great deal more information. Free clinics for venereal diseases have not been in existence very long, and our great object for some time must be to encourage early and continued treatment. No doubt we shall before long have to adopt some modified system of notification and restriction for those cases which will not submit to adequate treatment. At the present time we have to trust to patients carrying out the precautions enjoined upon them by the medical officers of the clinics or the private medical practitioners who are responsible for their treatment. We have said that more information is needed. The information we have in mind is already in the possession of the medical officers of the venereal disease clinics all over the country. It only requires to be tabulated and collected. A considerable section of the public have an altogether exaggerated idea of the danger of contracting venereal diseases "accidentally" or "innocently." Medical men, in the absence of reliable statistics, have only vague opinions on the subject. Even the individual medical officer of a clinic who may be treating either gonorrhœa alone or syphilis alone, has only his own experience as a guide and may not have attempted to classify the cases coming under his ken as to whether they were acquired accidentally or in the ordinary way.

We have had the advantage of obtaining the experience of one medical officer of a venereal disease clinic who had to deal chiefly with syphilis, and it may be useful to give the results of his experience shortly. The cases of gonorrhœa seen by this medical officer were mostly among women, and the number of cases not contracted through sexual intercourse was very few. A few cases of gonorrhœal vaginitis among girls were met with, contracted by sleeping with infected mothers or sisters, but no cases of what might be called "accidental" infection, such as through the use of infected public conveniences. The contacts infected were, in fact, bed-contacts. The experience of this clinic was, however, chiefly with regard to syphilis. Of 1500 cases of syphilis admitted for treatment, there were only 10 cases that had not been acquired in the ordinary way through sexual intercourse. Of these 10, two were medical men with primary sores on the fingers contracted as the result of operations; one was a baby of 18 months old, infected by sleeping in the same bed with an uncle and aunt, who both had florid syphilis; one was a girl of 11 who had slept with a syphilitic elder sister; and another was a girl of 11 who was thought by a syphilitic sister, aged 19, to have been infected by herself. Two of the remaining cases, a girl aged 12, and a boy aged 7, were members of a family of which the mother and father had syphilis. The father died, and it was thought that the girl contracted the disease from nursing the baby which had congenital syphilis and subsequently infected her younger brother. Of the three remaining cases: (1) a girl aged 24 had a chancre of the lip 14 days after a wedding dinner at which she drank from a glass of wine after the bride, who was at the time suffering from syphilis. This girl was, however, keeping company with a soldier about this time and became pregnant. (2) In the case of a boy aged 10, with a papular secondary rash and no history of any primary sore, the source of infection was never elucidated. (3) A soldier developed a chancre on the top of the scalp from an infected glove during a boxing contest.

The experience of this one clinic goes to show that the risks of accidental infection run by the public from public conveniences, the use of cups, forks, and spoons, &c., are remote. Out of 1500 cases only 10 were infected in an extraordinary manner. Of these 10 two were examples of the well-known risks run by surgeons, five were examples of intimate family or bed contact, the wedding-dinner case may have been acquired in the ordinary way, one case resulted from a boxing contest, and the last remained a mystery. It must always be a tragedy for any person to acquire syphilis or gonorrhœa in an accidental or innocent manner, and it is a very uncomfortable thought that we may have our food prepared, our hair cut, or be shaved by attendants who are suffering from an infectious stage of syphilis. It may be, however, that the real risk is a very remote one. We ought to know the facts as far as they can be ascertained. Venereal disease clinics have been in operation long enough to afford valuable information. We suggest that the Ministry of Health might usefully address inquiries to the medical officers of all the clinics in the country for the purpose of having the information in their possession tabulated and collated with a view to ascertaining the approximate percentage of venereal disease which is acquired in what we may call an "accidental" manner. When this has been done we shall be in a better position to consider what restrictive legislation is necessary in the case of persons suffering from an infectious stage of a venereal disease.

A Three-cornered Problem of Infection: Doctor—Patient—Employer.

Whilst the question of obligatory notification of venereal disease still awaits settlement, serious problems arise to emphasise the need for protecting the community against the danger of infection from recalcitrant individuals suffering from gonorrhœa or syphilis. A correspondent has asked us to comment upon one such problem, of which the pertinent facts may briefly be stated as follows:—

> A cook had been attended by her medical practitioner for a considerable time. She informed her mistress that she was suffering from internal discharge. She became worse and was ordered to bed. The lady of the house was unable to obtain any information from the doctor as to the nature of her servant's illness, but was informed by another maid that the cook was suffering from venereal disease, and that the doctor had promised not to disclose the nature of her ailment. The patient was ordered to take a hot bath every evening, there being but one bath in the house and some 12 people to use it. Not wishing, however, to dismiss her cook unless there was serious risk, the mistress again attempted, this time through a friend, to obtain information from the doctor. The latter made no positive statement, but the general impression gathered by the interrogator strengthened the suspicion that the patient was suffering from venereal disease. Eventually the mistress, after consultation with her own doctor, gave notice to the cook, who thereupon left.

The essence of the problem appears to be this. When a medical man is attending for venereal disease a patient whom he knows to be living under conditions which are a menace to the health of others what attitude should he adopt? Certainly he cannot give any information to the employer as to the nature of the patient's illness, but he can impress upon the patient the necessity which exists for giving up the situation at once. It may be objected that the patient will refuse to carry out this injunction. We believe that the practitioner endowed with tact and a knowledge of human nature would practically always achieve his object. The difficulty then arises that patients suddenly leaving their situation would be unable to find residential accommodation while undergoing treatment without attracting an undesirable degree of notice. This points to the establishment of hostels, both for men and women, where they could obtain treatment, or whence they could go to clinics for that purpose. Many such patients must of necessity be received free of charge, whilst others could contribute towards their maintenance. Any expense incurred by the State would be counterbalanced by shortening the period of wage-earning incapacity and preventing extension of infection. In the particular case on which comment was desired it seems to us imperative that professional confidence should be respected, and therefore the medical man acted with propriety in abstaining from informing the mistress, directly or indirectly, as to the condition of the servant. Nor was the doctor bound by law or ethics to insist upon the patient informing the mistress of the nature of her disease. It was, however, his duty to impress upon the patient the necessity of at once vacating her post. In order to facilitate the desired action the medical man might well have given to the patient a certificate to the effect that her physical condition was such as to preclude her from remaining in her situation. If she then voluntarily informed her employer of the nature of her disorder, such a course would facilitate any measures of disinfection. There remains the exceptional case in which the patient refuses after warning to put into practice the doctor's advice. Apart from any wide measure of compulsory notification, it is evident that the hands of the medical man should be strengthened to deal with such a situation. Any patient who has received a written statement from a doctor that he is a danger to the health of his employer and that he should at once vacate his employment, if he then fails to do so, should be notified as wilfully subjecting others to the risk of venereal disease. Legislation is desirable to empower such notification and determine the penalty for default.

A Red Cross Conference.

The first of the Red Cross regional conferences on venereal diseases to be held in Europe will convene at Copenhagen on May 20th, under the auspices of the League of Red Cross Societies. The Danish Red Cross Society will act as host and convener of the conference. The national Red Cross Societies of Holland, Great Britain, Norway, Sweden, Germany, and Finland have been invited to participate. Each Red Cross Society participating will send official delegates, and it is expected also that the governments of the countries concerned will be represented.

The problems to be discussed at the conference are outlined below:—

General summary of conditions in each country.
Medical measures against venereal diseases.
Educational measures against venereal diseases.
Special problems, including supply and costs of arsenical compounds for the treatment of syphilis, the possibility of establishing an international standard for the export and import of such arsenical compounds; the provision in important ports, by international agreements, for the treatment of cases of venereal diseases among sailors, and measures to be taken in connexion therewith; the part of the Red Cross in combating venereal diseases, its relation to government and voluntary agencies.

Following the first European regional conference in Copenhagen, the League of Red Cross Societies expects to arrange other regional conferences in other parts of Europe and subsequently in other parts of the world. The inception of such a conference by the League of Red Cross Societies indicates that the combating of the venereal diseases is recognised as an appropriate function of Red Cross societies. Considerable scope exists at present for such activity on the part of Red Cross Societies in the directions of popular education as to the causes and results of these disease and the provision or extension of facilities for the treatment of existing infections. Both these branches of antivenereal work are very suitable for adoption by Red Cross societies as a part of their programme of coöperation with public health authorities. In this country the instruction of young people, parents, teachers, and others in regard to the dangers of venereal diseases has been undertaken successfully by the N.C.C.V.D., working in close contact with the Ministry of Health and receiving the support and assistance of the British Red Cross Society. We are glad to learn that the National Council will be represented in the British delegation at Copenhagen, and that an exhibit of their educational methods and those employed by the American Social Hygiene Association will be a prominent feature of the conference.

In countries, as in Great Britain, where the Government is alive to the necessity for providing treatment for all sufferers from venereal diseases, and where an influential society for combating venereal diseases is in existence, the Red Cross may probably find it sufficient to content itself with lending moral and financial support. In countries where these factors are lacking or are inefficiently organised the Red Cross could advantageously play a more active rôle in providing education and treatment, and urging the adoption of such measures on the responsible authorities. The training of doctors and nurses, and the encouragement or endowment of further research as to the diagnosis and treatment of syphilis and gonorrhœa might well be considered desirable functions to be fulfilled by a Red Cross society. From the broader international point of view, it seems desirable to urge the development of a common basis for the prosecution in various countries of an active venereal campaign. As is well known, the outlook upon the venereal diseases varies greatly in different nationalities, and there appears to be a necessity for the exchange of views and opinions as to the practicability or otherwise of methods adopted in different countries for the combating of venereal diseases. For example, the outcome of the controversy in England as to immediate self-disinfection will be a valuable contribution to the campaign against venereal diseases in other parts of the world. The institution of such an organisation for international coördination and coöperation in measures against venereal diseases appears to be imminently desirable. The nucleus of such an international bureau exists in the League of Red Cross Societies, whose Division for Combating Venereal Diseases has been organised to act as a clearing-house for information and which is in communication with national societies and leaders in every part of the world.

AN INQUIRY INTO THE SALE OF DISINFECTANTS.

IT is extremely unfortunate that the views of the general public on the scientific uses of disinfectants are not so sound as they should be. In only too many illnesses the public thinks that disinfectants ought to be used to kill germs in their own body, or to prevent disease in others by the killing of germs in surrounding patients. Fortunately, the vast majority of patients are prepared to accept their doctor's advice before they start trying to kill the germs in their own body. The magic word "poison," which the Poison and Pharmacy Act, 1908, requires should be placed on receptacles of most poisonous substances, suffices to prevent the public from drugging themselves to the extent of harming their persons. Disinfection of the surroundings of patients is, of course, a wise procedure in the case of some illnesses, although disinfectants have been overdone. It is almost needless to point out that we are greatly handicapped in dealing with infectious disease, since we know so few of the germs causing infectious disease, and so little of the factors concerned in their spread.

Public Ignorance of the Function of Disinfectants.

Dr. T. W. Naylor Barlow some ten years ago published a valuable paper in *Public Health*, part of which dealt with the dangers of disinfectants. Quoting the medical officer of health of the county of Roxburgh of that time he stated that disinfection should be applied after cleaning and not in the place of cleaning. Dr. Barlow held that many housewives, especially those among the less intelligent classes, think that if they scatter plenty of disinfectant about no other precautions are necessary to prevent the spread of infectious disease, and he gave chapter and verse for his opinion. He also complained of the condition of ashbins and ashpits which were wrongly used, and pointed out that it was impossible to educate the public in the correct use of ashpits and ashbins if a health or cleansing department served out to the public some deodorising powder, not a disinfectant, to cloak their own carelessness. Quoting Dr. Meredith Richards, he agreed that the time had come when hygienists should free their minds from cant and teach both their authorities and the public that chemical disinfectants are of strictly limited utility, and that by far the greater part of the money now spent thereon would be better expended on soap, soda, and scrubbing-brushes. Dr. Barlow holds that disinfection of bedding in a steam disinfector is all that is necessary; he does not believe in the spraying of walls and gaseous disinfection for the reason that the organism cannot be brought into contact with a sufficient strength of the liquid or gas for a sufficiently long time. Although it is, perhaps, no longer the fashion nowadays to disinfect everything and everybody, yet we have not yet reached the position of complete sanity with regard to disinfection. Is it only in towns whose modes of thought are early Victorian, not to say pre-scientific, that disinfection is carried out after measles, for instance? Bleaching powder was used in the army to disinfect the ground around camp kitchens, stand-pipes, &c. At a recent large Boy Scouts Camp the ground near the urine pails was liberally bestrewn with a dark reddish-brown powder, which a local shopkeeper prominently advertised, basing his recommendation on the fact that it was used by the camp authorities.

But municipal authorities themselves are at times at fault. A well-known seaside resort used till recently to sprinkle its streets with sea-water. Although economy was one reason for its employment, a second aim was to disinfect the road surfaces. The salt water proved to be harmful to the wheels and tyres of vehicles, and the experiment was in consequence abandoned. Disinfectants are, however, thought to be of such importance in at least one town that a special subcommittee meeting is held annually to consider the tenders for disinfectant solutions and powders. To this meeting the sanitary inspector is invited, but not the medical officer of health. The result is the expenditure of a sum of money, admittedly small, which could be saved with no detriment to the public health.

Nevertheless, disinfectants have rational uses. Probably the majority of public health workers hold that micro-organisms are the main cause of infectious diseases, and would agree that disinfectants are of use in connexion with certain infectious fevers. Whether disinfection is necessary after cancer must remain a moot point until the question of the infectivity of cancer, a question which many consider is definitely settled in the negative, has been as finally decided as such a problem can be decided.

At the conference at the Royal Sanitary Institute held the summer of last year, Professor Henry Kenwood's proposal was adopted, that the Government should take up the control of the sale of disinfectants and that the sale of any liquid as a disinfectant in the public interest and on public health grounds be controlled by legislation, which should demand that any liquid "disinfectant" should have a carbolic acid coefficient (as tested by an approved method) of at least one. Penalty should be imposed for any false or misleading statements as to the germicidal value of a disinfectant, and for any misleading instructions with reference to the effective use of a disinfectant. Already the navy, army, and Government departments, and many local sanitary authorities protect themselves by the stipulation of their tender, and it is only the private purchaser who is left unprotected.

Nature of Disinfectants Stocked at Oilshops.

Inquiry has been made at some oilshops as to the nature of the disinfectants stocked and the approximate quantity sold, with the following result in two urban areas :—

I.

Shop No. 1.—Jeyes' fluid (8 oz. bottles), 3 weekly; Sanitas fluid, 1 weekly; carbolic fluid (loose), ½ gal. weekly; carbolic powder (packets and tins), 6 weekly.

No. 2.—Jeyes' fluid (bottles), ½ to 1 gal. weekly; Sanitas fluid (bottles), 2 or 3 pints weekly; carbolic fluid (loose), 2 gal.; Sanitas powder, 2 or 3 lb. weekly; Jeyes' powder, 3 lb. weekly.

No. 3.—Carbolic fluid (loose), pint weekly; Jeyes' fluid and Sanitas fluid (bottles), each 1 per 3 weeks; carbolic powder, 2 lb. per annum.

No. 4.—Jeyes' fluid (bottles), 2 to 3 gal. weekly; carbolic powder and Sanitas powder, each six tins weekly.

No. 5.—Jeyes' fluid, Sanitas, Milton, and carbolic (loose) (bottles), each ½ gal. weekly; Jeyes' powder and Sanitas powder (tins and packets), each 3 to 4 lb. weekly.

No. 6.—Jeyes' fluid (bottles), carbolic fluid (loose), Sanitas fluid (bottles), each 1½ gal. weekly. Condy's fluid (bottles), 2 monthly; carbolic powder (tins), 6 weekly.

No. 7.—Jeyes' fluid (bottles), Sanitas fluid (loose and bottles), carbolic fluid (loose and bottles), each ½ gal. weekly.

No. 8.—Jeyes' fluid; Sanitas fluid; Smith's fluid (bottles); carbolic fluid (loose); Smith's powder (packets).

No. 9.—Sanitas fluid (loose); Jeyes' fluid (bottles); Sanitas powder and carbolic powder (packets).

II.

Shop No. 1.—Liquid carbolic, about a gallon weekly.

No. 2.—Liquid carbolic, about half a gallon weekly.

No. 3.—No. 2 disinfecting fluid (under 3 per cent. carbolic), Jeyes' fluid, and Sanitas.

No. 4.—Dussek's fluid, Jeyes', Milton, and Sanitas.

No. 5.—Carbolic fluid, Jeyes', and Sanitas. The carbolic fluid on sale is of ordinary commercial standard and the sale is small, varying according to the weather conditions.

No. 6.—Disinfectant fluid.

No. 7.—Sanitary fluid in 5 gal. drums. No strength stated.

No. 8.—Wholesaler. Best carbolic disinfecting fluid. No strength stated.

No. 9.—Bought as soluble disinfectant fluid from wholesaler. No strength stated.

No. 10.—Bought from wholesaler as best carbolic disinfectant fluid. No strength stated.

In a provincial town inquiry at the oil shops elicited the following approximate sales:—

III.

Shop No. 1.—C.D. fluid, 1 gal. weekly.

No. 2.—Cresol, 1 gal. in summer time weekly.

No. 3.—Cresol, said to be 16 per cent. solution, 1-2 gal. weekly.

No. 4.—Sanitas, 2 gal. weekly.

No. 5.—Sanitas, only a small quantity weekly.

No. 6.—Cresol, 2 or 3 gal. weekly.

All the shopkeepers sell in pennyworths and twopennyworths, and customers bring their own bottles.

Poisoning by Disinfectants Unusual.

The phenoloid class of disinfectant is as a whole relatively not poisonous. The physical consistence of most of these disinfectants is such that it is not easy to drink a large quantity of them. Small quantities even of the undiluted solution are obviously harmless. For some considerable time, in more than one fever hospital, it was the practice to apply undiluted izal to the throat and no harmful results accrued from the quantity which must necessarily be swallowed. Although cases of poisoning with lysol are recorded, accidental poisoning with this class of compound is very unusual, the colour, appearance, viscidity, odour, and taste are very manifest, and, for the reason cited above, a small quantity, possibly even a mouthful, taken accidentally would in all probability not do much harm. As regards exhibition with criminal intent, to be effective the substance would have to be present in such strength that its taste and smell would at once be apparent. If a person wishes to commit suicide by poison the facilities which already exist for obtaining poison—e.g., weed-killer, hydrochloric acid, sulphuric acid, nitric acid, soluble salts of oxalic acid, copper sulphate, turpentine, lead salts, especially lead arsenate, are so abundant that a determined man or woman would certainly be able to get one of them. A leaflet issued by the Board of Agriculture informs the public how to get weed-killer and lead arsenate.

It has been the aim of manufacturers of disinfectants to produce substances with a high coefficient. Much of the money that has been wasted on so-called disinfectants has been wasted by the public being persuaded to purchase a well-advertised substance of low coefficient value. It would seem that the time has come to allow the wider sale of these phenoloid compounds. Apparently there is no valid objection to their sale by oil-shops or ironmongers, although it would obviously be futile to limit the strength of disinfectants sold at these shops to a point at which they are quite ineffective. Such disinfectants are diluted more for the profit of the vendor than to render them less poisonous. A difficulty may, however, be found in a recent legal decision which, we are informed, makes it necessary to label these substances as poisonous.

Obligation to Label Disinfectants as Poisons.

This legal decision would appear to be based on the word homologues in the text of the Pharmacy and Poison Act, 1908, which regulates the sale of certain poisonous substances. The list of these, enumerated in the schedule, includes carbolic acid and liquid preparations of carbolic acid and its homologues containing more than 3 per cent. of these substances, except preparations for use as sheep-wash or for any other purpose in connexion with agriculture or horticulture contained in a closed vessel distinctly labelled with the word "poisonous," the name and address of the seller, and a notice of the special purposes for which the preparations are intended. Part 2 of the schedule also specifies the articles to be deemed poisonous within the meaning of the Act. "All preparations or admixtures which are not included in Part 1 of this schedule, and contain a poison within the meaning of the Pharmacy Acts, except preparations or admixtures the exclusion of which from this schedule is *indicated by the words* therein relating to carbolic acid, chloroform and coca, and except such substances as come within the provisions of Section 5 of this *Act*." Section 5 (1) states that:

> "It shall not be lawful to sell any substance to which this section applies by retail, unless the box, bottle, vessel, wrapper, or cover in which the substance is contained is distinctly labelled with the name of the substance and the word 'Poisonous,' and with the name and address of the seller of the substance, and unless such other regulations as may be prescribed under this section by Order in Council are complied with; and if any person sells any such substance otherwise than in *accordance with the provisions* of this section or of any Order in Council made thereunder, he shall, on conviction under the Summary Jurisdiction Acts, be liable for each offence to a fine *not exceeding* £5.
>
> (2) The substances to which this section applies are sulphuric acid, nitric acid, hydrochloric acid, soluble salts of oxalic acid, and such other substances as may *for the time* being be prescribed by Order in Council under this section."

It is doubtful whether, as a matter of policy, it is advisable to label these phenoloid disinfectants as "poisonous." Such a label focuses attention on this quality; possibly the community would be best served by labelling them "Not to be drunk." A fundamental principle is that a disinfectant should be applied in sufficient strength—the public, however, often think they are buying true disinfectants, whereas they receive deodorants. It would seem probable that an assistant in an oil-shop would not be so likely as a qualified pharmaceutical chemist to know the scientific value of a commodity he sells. The assistant or proprietor of a retail Italian warehouse might be liable to judge a disinfectant by its æsthetic properties, such as its smell or colour when mixed with water. The chemist, with his association with the medical profession, would be more willing to give credibility to the statements of members of the medical profession, the eminence and scientific qualifications of whom he would be more or less able to judge. Possibly, however, these disadvantages could be removed in time, at any rate, if the public is educated by disinterested scientists, including medical officers of health, who should be able to do much by enlightening those members of their health committees who desire information.

MEDICINE AND THE LAW.

Evidence as to the Time of Death in Murder Trials.

A CORRESPONDENT invites our attention to the important nature of the evidence expected from medical men in cases of death involving criminal charges, where the witness is asked to describe the condition of a dead body when he first saw it, and to state his conclusions as to how long previously death had taken place. Our correspondent further suggests that the text-books are less informing than they might be on the subject, and that an authoritative pronouncement could usefully be made upon the matter. He also points out the necessity for taking into account circumstances which vary in each particular case, but which are generally capable of being definitely ascertained. The subject is no doubt one of considerable interest owing to the fact that the evidence referred to is very frequently required in order to establish the guilt or innocence of a person accused of murder. To establish the time of death where a body has been found within a few hours is one thing, but it is quite another, and often even more important, where a long time has elapsed. The murderer Crippen would not have been convicted if the remains found under the kitchen floor of the house, which he had occupied, had been in a condition inconsistent with their having been placed there during his tenancy. The cases range, therefore, from such as his, to others of the nature of the Eastbourne murder referred to by our correspondent, where death had taken place within a few hours and the vital question was within how many. With regard, at all events, to occasions where the shorter time is involved, the collection of information of an authoritative description need not be difficult, and its publication would be of distinct service. It would imply that competent observers should avail themselves of such opportunities as many general hospitals could supply for watching the development of the various phenomena observable in dead bodies where violent or unnatural death has taken place. Record of surrounding conditions would be made, and would include the mode of death, physical details likely to affect post-mortem developments, and conditions of exposure, atmosphere, and temperature, to which the body was subjected. Contribution might further be made by those who have had such vast recent experience of the phenomena accompanying death upon the battlefield. The whole would have to be carefully collated and scrutinised, when it is quite possible that a monograph dealing with the subject suggested might prove a valuable contribution to forensic medicine, one of practical use to those who on rare occasions may be confronted by a duty lying outside the path of their daily experience.

Property in Bodily Organs.

In a recent number[1] of a Berlin medical paper Dr. Arthur Weil deals with certain practical and legal difficulties arising from the transplanting of sex glands according to Steinach's teaching of rejuvenation. The article suggests as the ideal the transplantation of healthy glands from normal relatives, if that were possible, and if not, the use of glands removed by operation on account of various morbid conditions, the difficulties of obtaining material being overcome by having a sort of exchange and mart in the surgical department of a large hospital. Apparently legal difficulty might arise in Germany in regard to the transplantation of a healthy testis, even with the consent of the donor, although not in the case of a gland removed on account of any medical reason. The proprietary right of the donor to any organ removed from him can in Germany pass over to the recipient by a mutual agreement, although no agreement is legally binding in regard to parts of the human body so long as they are still in organic continuity with it. The author suggests that the time-honoured practice of castration would be found to have some bearing on the legal position. In this country we are not aware that anything in the existing law would prevent a man agreeing to part with any portion of his body to another with or without consideration for so doing, or would prevent a surgeon from performing the required operation. The transfusion of blood affords a tolerably close parallel so far as questions of principle are involved. This, however, is not to be taken as any decision that public opinion would endorse such transfers as those suggested, either on the part of transferrer or transferee, or of the surgeon. We have here in mind the possibility that a wealthy man might desire to acquire the desired organ from a poor one. It is in such a case that odium would readily attach to the proceeding; where the transference was an act of self-sacrifice on the part of the transferrer it might be different. In any event the bargain to transfer would probably be held to be contrary to public policy, and could not be enforced in a court of law. Where the carrying out of such a bargain had for its result any injury not contemplated by one of the parties to it, the surgeon would find every effort made to attach responsibility to him, and a heavy weight of prejudice in the scales against him. In the second class of cases referred to, that of glands removed by operation on account of morbid conditions, it is suggested that transfer might take place through arrangements made by the surgeon and that in a hospital there might be organised a system by which the removed gland would be used for the benefit of another patient. Through such an exchange department in any large institution, the transferee would gain without the transferrer being aware of it, or at any rate without his knowing to whose welfare he had contributed. At the first glance this may appear practicable and not difficult to arrange. In such a system there would be no question of a man allowing himself to be mutilated for the sake of pecuniary gain, but the carrying of the transaction out would have to be subject to precautions in order to prevent serious scandal. There would always be a danger that the patient, whom we have called for convenience the transferrer, would complain that he had been operated on unnecessarily in order that someone else might gain thereby, or to enable the surgeon to enlarge his knowledge by an interesting experiment. Surgery does not indulge in secret remedies, so that the fact of such measures as those involved being in use would be generally known, and such trouble as might arise would find its way with every kind of exaggeration into the lay press. Accusations would be easy to make that would be difficult to disprove, and a charge of malpraxis might at any time be launched against a surgeon or a hospital to the serious detriment of either. There are occasions where the prudent are justified in waiting to profit by the experience of others.

A MONTHLY RECORD OF ATMOSPHERIC POLLUTION.

METEOROLOGICAL OFFICE: ADVISORY COMMITTEE ON ATMOSPHERIC POLLUTION: SUMMARY OF REPORTS FOR APRIL, MAY, JUNE, JULY, 1920.

April.

Place.	Rainfall in millimetres.	Metric tons of deposit per square kilometre.								
		Insoluble matter.			Soluble matter.		Total solids.	Included in soluble matter.		
		Tar.	Carbonaceous other than tar.	Ash.	Loss on ignition.	Ash.		Sulphate as (SO_3).	Chlorine (Cl).	Ammonia (NH_3).

---

* Rochdale figures are average for May and June. Ti. = Total insoluble. Ts. = Total soluble. † Bottle broken.

"Tar" includes all matter insoluble in water but soluble in CS_2. "Carbonaceous" includes all combustible matter insoluble in water and in CS_2. "Insoluble ash" includes all earthy matter, fuel, ash, &c. One metric ton per sq. kilometre is equivalent to: (a) Approx. 9lb. per acre; (b) 2·56 English tons per sq. mile; (c) 1 g. per sq. metre; (d) 1/1000 mm. of rainfall.

The personnel of public health authorities concerned in the supervision of these examinations and of the analytical work involved remains the same as published in previous tables. The analyses of the rain and deposit caught in the gauge at the Meteorological Office were made in THE LANCET Laboratory.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

Reciprocity of Medical Diplomas Between Austria and Czecho-Slovakia.

AFTER protracted negotiations an understanding has been arrived at between the Governments of Austria and Czecho-Slovakia which settles some of the numerous misunderstandings arising out of the disruption of former university links. There is now mutual recognition, between the republics, of the validity of medical degrees and diplomas obtained before Nov. 1st, 1918, at any of the universities now belonging to either State. These diplomas entitle their holder to practise in the numerous health resorts of the two countries (Carlsbad, Marienbad, Franzensbad, Hall, Baden Pistyan, Ischl, &c.). Furthermore, such diplomas are necessary for doctors who wish to practise in the hospitals and medical institutes of either country, but are not valid for regular medical practice outside these institutions or in other places than health resorts. Holders of diplomas obtained after that date must apply for permission if they wish to practise outside their own country, but this permission will be granted on very liberal conditions. In the frontier districts, where the population is very much mixed, doctors of either nationality may be consulted.

Increase of the Numbers of Out-patients in Hospitals.

Although the reports of the Board of Health show the health of Vienna to be improving, the numbers of out-patients in the ambulatories is constantly increasing. It is true that during the last few months of the war the conditions were still worse, but even so they are now most appalling. The lack of beds in hospitals prompts many patients to turn to the out-patient departments for help, where they are admitted only if they produce a certificate proving them to be paupers. Hundreds of such persons flock daily to the clinics. Labourers and factory hands were formerly the most frequent attenders in these crowds, but now they have disappeared, and the former middle-classes predominate, as they cannot afford to pay the private doctor's fee, and do not belong to a sick club. The ambulatories most frequented are those for diseases of women and children and for venereal diseases; the ophthalmologic clinics are also overcrowded at present; in the departments for children's diseases the number of babies and infants is markedly less than a few years ago—the result of war and the time of so-called peace.

Serious Position of Dental Practitioners: Medical Strike in Styria.

Within the last few weeks the medical profession has been considerably alarmed by the attitude of the Government towards a problem which was thought to have been definitely settled some time ago. As pointed out in a previous letter (vide THE LANCET, March 26th, p. 664) relations between the dental surgeons and the dental mechanics had become very strained; the mechanics demanded the right to perform minor surgical operations, including extraction of teeth. Whilst the doctors refused to admit such a right, the Government offered its services as mediator, and an understanding was arrived at. A Bill was drafted, to be brought before the National Assembly, which permitted the present practising mechanics to perform minor operations—e.g., lancing an abscess or filling teeth, but not extraction or other more highly technical procedures. In future, however, no new licence for the practise of dentistry was to be granted to the dental mechanic. But the matter has now assumed a different aspect; the leaders of the dental mechanics' union refused to accept this undertaking, and bought about a strike of mechanics employed by dental surgeons, whilst they themselves continued working for the public as formerly. They succeeded in bringing the present Government over to their side, and in spite of all protests from the medical profession a Bill was carried in the National Assembly giving dental mechanics practically the same rights as those pertaining to fully qualified doctors of medicine. It is true that the Bill provides for an examination to be passed by future mechanics before they may practise on human beings; the examination is to comprise anatomy, biology, pathology, and physiology of the mouth and teeth; but this measure of protection is regarded by dental surgeons as a farce. There will thus be two kinds of dentists in Austria—fully qualified doctors of medicine with six to eight years of hard scientific study behind them, and mechanics uneducated in general medicine, the latter having equal rights with the former, and being permitted by law to meddle in surgical contingencies with which they may not be competent to deal. This breach of the hitherto strictly observed law that no lay person shall be permitted to treat pathological conditions of the human body has naturally aroused great indignation amongst medical men; many suggestions have been made as to means of rendering protest effective, including the unpopular proposal of a medical strike. In Styria the doctors at once refused to coöperate with the local boards and Government officers in all public health affairs. Notification of disease, coroners' work, and inspection of meat and cattle have been refused. In Vienna, the medical organisation has taken up the challenge too; and the Medical Council is acting on the same lines, having, for instance, refused to give its opinion on the draft of the new law now under consideration, dealing with hospitals and charity institutions. All circles of the profession are unanimous in opposing the attitude of the Government, which is regarded as promoting a revival of medical quackery. The profession is not opposed to legislative reforms to improve the present relations between the hostile groups, but it refuses to be excluded in the process of settling such vital problems, especially after an agreement had been arrived at previously.

Contract Practice for Persons Employed by the State.

An experiment, conducted on a large scale from the outset, which may now be stated to have proved successful, has shown that the needs of the profession and the public may be easily reconciled with each other. In an agreement signed at the end of January, the State and the medical organisation have established a compulsory sick club for all State officials throughout the country. These officials number about 150,000; their wives and children are accorded the same rights in the club, together with the 25,000 State pensioners; the number of persons thus insured against illness amounts in all to over 400,000. The difference between this sick club and the other krankenkassen is the rate of payment. Members of the latter pay a certain monthly salary to their doctor, whatever his work be. The State sick club pays a fixed fee for each consultation or call. Any practitioner desiring to work under this contract is admitted to the test of doctors; the patient may select any one from this list he likes. If he chooses a man living away from his district he must pay an excess or "distance" fee, but gets refunded so much, as the doctor is entitled to charge in his own district only, according to the contract. As a rule the doctor gets 34 kronen for a first examination and for the subsequent consultations half that fee. For a call at the patient's home twice as much is charged; for a night call 100 per cent. more is added. Special services are paid at the rate of one to four points extra, each point being 10 kronen; for instance, the application of an extensive bandage, a hypodermic injection, a splint, a catheter, &c. Specialists can be consulted only if the general practitioner so desires. Their fees are much higher—100 kronen first examination, 50 kronen for subsequent consultations. Here, also, calls at the patient's house are 100 per cent. higher, night calls and extra work not involved in the regular examination are paid in addition. The doctor is entitled to charge an extra "distance" fee if called to a patient outside of his district, but this the patient must find out of his own pocket. As regards the funds of the State sick clubs, these are raised by regular contributions by the insured persons and the State. The State officials pay 1½ per cent. of their salary towards this fund, and an equal sum is paid by the

State. The result of these payments is calculated at 60,000,000 kronen a year, sufficient to pay 400 kronen a year for the illness of 150,000 members—figures obtained from the experiences of other sickness insurance clubs. The understanding was arrived at for a period of three months, subject to rearrangements as general conditions might require. It was found to be working very satisfactorily for both parties; it was therefore renewed on May 1st, the fees being increased by mutual understanding, for the period of the next three months, thus reaching about 50-60 per cent. of the fees of general private practice.

Discovery of a Warm Iodine Spring in Austria.

Thermal water, highly charged with iodine, has recently been discovered in Upper Austria, not far from Linz, coming up a shaft more than 1500 feet deep. The temperature of the water is 36° C. (97° F.), this being by far the hottest of all thermal iodine waters in Europe. The owner of the springs did not know the value of the waters, and refused to hand his well over for public use. Thereupon the Local Government Board applied to the Ministry of Public Health, and the existence of this valuable spa only then became known to the latter body. Expropriation has been contemplated, as the owner will not admit that the community is entitled to the benefits of this rare natural gift. Hitherto the strongest iodine waters were those at Hall, also in Upper Austria; the latter have a temperature of only 11° C. (52° F.), and are extensively used both in the drinking cure and in the shape of "Hall iodine salt." Since the war the combined treatment with salvarsan and iodine baths in Hall has been very much recommended in this country for syphilitic disease of the tertiary stage, and medical circles expect even better results from the new thermal waters, the capacity of which is over 60 litres (15 gallons) per second.

May 4th.

ROUMANIA.

(FROM OUR OWN CORRESPONDENT.)

Food Adulteration and Preservation.

Dr. Constantinescu, chemical analyst at the Department of Agriculture, read a paper at the Medical Club of Cluj on the above subject. He said that the necessity of preserving food in some way had been recognised since man emerged from his uncultured state. The development of the science of chemistry had placed in the hands of the manufacturer means before unknown of preserving foods, but also of matching them in colours simulating quality. He believed the education of the public in the artificial colouring of foods to be quite as effective as legislation. After April 20th he said the food law would require that all food products entering or leaving this country (meat conserves, vegetable conserves for the army), should, if artificially coloured, bear a label with a statement to that effect. No colouring material need be declared, excepting only sulphate of copper. His advice to food makers was to cease using colours, especially if the colouring matter is under suspicion of any kind. He considered that antiseptics should never be put into foods, except when absolutely necessary, unless the consumer orders them himself, but in his opinion it is legitimate to use salicylic, boric, and sulphurous acid (the last in infinitesimal doses), as employed in the fumigation of dried fruits, and the burning of the sulphur linen in wine barrels, a method which has come down from antiquity. When, as at the present time, it is employed in enormous quantities for preserving a poor vintage and for placing wine on the market before it is properly matured, he declared its use to be unpardonable.

Medical Sociology.

A society for the study of questions of social medicine and hygiene and medical statistics was formally constituted in Bucharest on April 9th at a meeting attended by a number of medical practitioners, political economists, and sociologists. The membership of the new society amounts to 31, and includes medical practitioners, official statisticians, and persons interested in social welfare.

Neglected Physical Signs in Diseases of the Chest.

Dr. Riemer calls attention to several physical signs first described by Dr. A. Grober in Germany, the presence of which he considers to be of some importance, in the diagnosis of intrathoracic diseases, with information gained by fluoroscopy. It is but little known, for instance, that difference in the size of the pupils is a common symptom of apex tuberculosis. The pupil of the affected side is generally wider, since the sympathetic nerve is irritated by the inflamed pleura. Another valuable sign is the behaviour of the veins of the chest if an expiratory effort is made with closed glottis as in Valsalva's method. Normally the vessels on both sides swell equally, but with tumours, aneurysms, &c., the veins affected by the compression will be more prominent. Normally, the pupils contract somewhat during expiration and dilate slightly with inspiration; with Valsalva's method there is a gradual, slight dilatation during the deep inspiration preceding the expiratory effort, and a gradual slight contraction during the latter. In disease the following variations occur: (1) Only one pupil will show normal contraction; the other will dilate, and on the side of the latter pathological lesions of definite localisation will be found in the thorax. (2) If both pupils dilate instead of contracting during forced expiration, the disease is bilateral. (3) If there is a difference in the size of the pupils during normal respiration and the dilated pupil widens still more during Valsalva's experiment, while the contracted one becomes normal, intrathoracic disease on the side of the wide pupil is probable. (4) If the pupils differ in size with quiet respiration, but dilate with Valsalva's method, bilateral intrathoracic affection is probable. If the smaller pupil becomes equal to or larger than the other one, the disease probably also affects both sides, if local disease or organic disease of the nervous system can be excluded. Absence of all these phenomena does not argue against intrathoracic disease; the percussion note obtained over the manubrium sterni is here of the greatest value. In new growth or inflammatory tumour of the mediastinum there will often be dullness with closed mouth and tympanitic resonance with open mouth, or tympanitic resonance with closed mouth and Wintrich's change of percussion with open mouth.

New Regulations to Prevent the Spread of Infectious Diseases.

For the Bill recently introduced by the Sanitary Board of Roumania the chief sanitarian has now substituted another, which not only gives authorities power to control persons suffering from acute infectious diseases, but also gives them sanitary control of the premises where such diseases exist. The Bill also confers powers for the regulation of burial of bodies of persons who have died of acute infectious diseases, and fixes fines and penalties for non-compliance with the rules made. It stipulates that the rules shall cover the following: (1) Reports from physicians; (2) quarantine and disinfection; (3) treatment of infected bedding and clothing; (4) care and burial of the dead in cases of contagious disease; (5) disinfection of conveyances; (6) admission and attendance of persons at public or private schools, asylums, hospitals, and compulsory vaccination and revaccination; (7) erection of a typhoid station, where patients convalescent after typhoid (typhoid-carriers) will be examined fortnightly for three months.

Death-rate in 1920.

The State Statistical Bureau, in its annual report, finds that, estimated by the death-rate from all causes, the sanitary condition of the Roumanian State (old Kingdom) for 1920 was unsatisfactory. There were 128,564 deaths reported, which is largely in excess of previous records. The annual average mortality for the past 20 years, including 1920, is 120,000. Of epidemic diseases, cerebro-spinal fever and measles alone have shown any material increase. There was an outbreak of the latter disease in several parts of the kingdom, beginning in March and continuing for several months. Typhoid was also responsible for many deaths; in Moldavia, the eastern part of the Old Roumania, the mortality from this cause was nearly double that of 1919. The chief cause for increase in mortality of 1920, however, has been pneumonia, with 13,500 deaths, against 11,470 in the preceding year. These figures were nearly reached in the worst influenza years (1917-18 and 1891-93). There were over 11,000 deaths from consumption; this figure also exceeds that of any previous year.

COUNCIL OF BRITISH OPHTHALMOLOGISTS: ANNUAL REPORT.

THE Council of British Ophthalmologists presented its annual report for 1920-21 to a meeting of ophthalmologists held on May 7th at the Royal Society of Medicine. The report opened with a record of appointments made at the first meeting of the session. Mr. J. B. Lawford was elected President in place of Sir Anderson Critchett; Sir George Berry and Mr. E. Treacher Collins were elected Vice-Presidents; Mr. J. Herbert Fisher, hon. treasurer; and Mr. Leslie Paton, hon. secretary. The following members were elected on the Executive Committee: Messrs. Fisher, Collins, Parsons, and Mayou, with the President and Secretary ex officiis.

In 1919 the Council issued a report dealing with the training and examination of ophthalmic surgeons; it was noted with approval that the following special examinations in ophthalmology have recently been established: M.S. London (Ophthalmology); M.S. Victoria University, Manchester (Ophthalmology); D.O.M.S. Conjoint Board, R.C.P. Lond. and R.C.S. Eng.; also that at the present time a committee of the Royal College of Surgeons of England is considering the question of creating a higher form of diploma in connexion with the Fellowship of the College. During the session the Council issued a report on the need for institutional treatment of children with contagious eye disease, which was forwarded to the Ministry of Health. As a result of this action beds are now available at the Metropolitan Asylums Board Ophthalmia School at Swanley for the treatment of London school children suffering from ophthalmia or other contagious diseases of the eye.

The Council has considered the question of sight-testing by opticians, and has prepared and approved a report on the subject. It is not proposed to publish this report at present. The Council has also prepared a report on the notation of cylinder axes, and still has under consideration the question of the standardisation of test types. A member of the Council has been appointed to serve on a joint committee consisting of representatives from the Illuminating Engineering Society, the Research Association of British and Allied Manufacturers, the British Scientific Instrument Research Association, the Institution of Automobile Engineers, the Commercial Motor Users Association, and the Electric Lamp Manufacturers Association of Great Britain, Ltd., on "Glare from Motor Car Head-lights."

The Council agreed to appoint a committee to consider the question of injuries to eyesight resulting from the use of strong lights in cinema studios, but as the Minister of Health referred the matter to the Departmental Committee on the "Causes and Prevention of Blindness," it was decided not to take any immediate action. An interim report of the Committee on "Eyestrain in Cinemas," on which the Council has four representatives serving, has been issued.[1] A committee has been appointed to consider the report of the Consultative Council of the Ministry of Health, in so far as it is likely to affect ophthalmic surgeons. This committee has already gathered a considerable amount of information as to the work done by ophthalmic surgeons for various public and State authorities. Another committee is considering the question of examination, treatment, and report of cases referred by public authorities to ophthalmic surgeons in voluntary hospitals.

Obituary.

GEORGE BLUNDELL LONGSTAFF, M.D., D.P.H. OXON., F.R.C.P. LOND., F.G.S., F.L.S.

DR. G. B. Longstaff died at his residence, Putney Heath, on May 7th, aged 72. The son of the late Dr. George Dixon Longstaff, of Wandsworth, he was educated at Rugby, at New College, Oxford, where he took a first-class in natural science, and at St. Thomas's Hospital, London, where he won the Mead medal. Graduating at Oxford in 1872, he proceeded to the M.A., M.B. in 1876, and to the M.D. in 1891. He became a Member of the Royal College of Physicians of London in 1877, the Fellowship being conferred on him in 1888. Dr. Longstaff devoted much time to municipal and philanthropic work. He represented Wandsworth on the London County Council from 1889 to 1903, and as chairman of the Building Act Committee took an active part in promoting and passing through Parliament the London Building Act of 1894. He was a Vice-President of the Royal Entomological Society and of the Royal Statistical Society, and was the author of "Butterfly Hunting in Many Lands." His smaller publications included articles on "The Geographical Distribution of Diphtheria"; Studies in Statistics: Social, Political, and Medical"; "Rural Depopulation"; and "A Contribution to the Ætiology of Rheumatic Fever." Dr. Longstaff was a born traveller, and his medical training added greatly to his interest in life and to his public usefulness. He never practised.

EDWARD WARD, M.B., CH.B. CAMB., F.R.C.S. ENG. (HON. CAUSÂ.),

CONSULTING SURGEON, LEEDS GENERAL INFIRMARY.

MR. Edward Ward, who was very well known as a surgeon in the North of England, died at Leeds on April 30th. He received his early education in Leeds, afterwards entering Trinity College, Cambridge, with the intention of studying for the law. He graduated B.A. in 1876, but on the death of his father decided to take up a medical career, and became a student at the Leeds Medical School, from which he qualified in 1881, following this up with the M.B., B.Ch. three years later. He then became resident surgical officer at Leeds General Infirmary, ascending the scale until he finally became consulting surgeon. The Royal College of Surgeons of England conferred upon him the honorary diploma of Fellow in 1904. Five years after he asked to be relieved from active duties at the Infirmary, the board putting on record their appreciation of a service extending over nearly 20 years. Mr. Ward occupied for a time the chair of surgery at Leeds University, and examined in surgery at the University of Cambridge. He also presided over the Leeds and West Riding Medico-Chirurgical Society. His sympathy and gentleness earned him abundantly the confidence and esteem of patients, and his professional colleagues knew the real worth behind a singularly unassuming manner. He had been in failing health for some years before his death.

THOMAS EDWARD HONEY, M.D. DURH., M.R.C.S., L.R.C.P. LOND.

Thomas Edward Honey, who died at his residence, Shutta, East Looe, on April 30th, was born in Devonport and received his medical education at St. Mary's, from which he took the M.R.C.S., L.R.C.P. Lond. in 1886 and the M.D. Durh. He practised for a short time in Devonport and became surgeon of the Provident Dispensary, Royal Albert Hospital; he subsequently entered the navy and retired as staff surgeon. During the war he offered his services to the Marylebone Infirmary, which, owing to the neighbouring infirmaries being reserved for the wounded, took in also the patients from Hampstead, Paddington, and Hammersmith. Dr. Basil Hood, medical superintendent to the infirmary, writes of him: "Dr. Honey volunteered to replace one of our younger medical officers who was joining up. He was then over 50 and had for some years retired to the country, which his soul loved. He stayed with us just over three years, much longer that he should have done had he considered his own health, in order to allow a colleague a rest. He was a model of conscientious care and attention, besides finding time to spend many an hour in kindly yarning with the old bedrid and helpless patients. But the strenuous work under difficult conditions undoubtedly aged him. The visiting committee, staff and patients all parted from him with keen regret." His death followed ten days after an attack of hemiplegia.

The Services.

THE MEDICAL SERVICE OF THE DEFENCE FORCE.

THE threat of a general strike with the possibility of lawlessness and disorder finding their opportunity in those affected by unemployment and privation called into existence a Defence Force of Loyal Citizens, and for the time this force remains in being, mobilised and equipped for the defence of the community. For any such body of men a medical service is necessary from the beginning, to deal with the sick and with the minor accidents and injuries resulting from training, while should the Force unfortunately be called on to act, an organised medical service will be valuable, not only for the Force and those with whom it comes in conflict, but for such civilians as involuntarily become involved in the area of strife. The Force is organised on the basis of army divisions and each division has the usual medical services, though on a modified scale. In addition to the regimental medical officers each division has three field ambulances (of two sections instead of three) and a sanitary section. The field ambulance is a mobile unit with mechanical transport and motor ambulances; and its two sections are equipped for the first aid, feeding, and temporary nursing of 100 men and for any necessary urgent operations. It has tentage on a small scale, but in this country suitable buildings of some kind would usually be available and would be used—their advantages are no longer outweighed, as in the war, by their conspicuous attractiveness for high explosives.

The Royal Army Medical Corps on many occasions in the past has provided equipment for 100 cases, and has attended to many times that number of sick. In any grave emergency in this country the personnel of the bearer squads would certainly be augmented by willing and expert helpers, in gathering patients from dangerous localities, and in evacuating buildings on fire, carrying the injured into safety or to receiving posts and dressing stations. As regards the medical establishments of the rear—casualty clearing stations and base hospitals—the Defence Force will depend on the excellent military and civil hospitals of the country. In some areas the military hospitals are at present acting as field ambulance hospitals for minor sick, and as clearing stations for more serious cases which are transferred to the nearest suitable civil hospitals. In other areas where no military hospital is available the divisional medical services evacuate the sick direct to the civil hospitals. No doubt in case of emergency the great voluntary and public hospitals would be able to expand their services as far as required, while their staffs include many with expert knowledge, both of the immediate and late surgery of military injuries. Many civil hospitals at the present moment have lessened their activities to conserve their coal and other supplies to enable them to continue, in case of a long-drawn-out struggle, to deal with urgent medical and surgical cases among the civil population in their areas, and in consequence a fair proportion of normal accommodation is vacant. Should this unfortunately be inadequate in any locality, most civil hospitals are generous in their allotment of floor space per patient, when judged from the standpoint of a casualty clearing station, and the accommodation would, no doubt, be expanded in crisis by obtaining beds and bedding from local resources, and by enlarging their staffs from the medical practitioners and volunteers, male or female, of the neighbourhood who have served in hospitals during the war. These from previous training could at once—and adequately—fill gaps in the organisation.

The personnel of the existing field ambulances of the Defence Force is composed very largely of ex-members of the R.A.M.C. with war experience. With these there are others, who have training in first aid and R.A.M.C. duties in the Territorial Army, and some medical students; some business men and shopkeepers, though without any experience, have come forward, and while learning their stretcher drill and first aid will probably in the end find employment as clerks or storemen. Others have experience of active service as fighting troops, and give the impression that they would prefer to be with their old arm, but that they might come into collision with some whom they know and like (though deploring their lack of clear vision in the present crisis). These men, I think, would be foremost to rescue in a real place of danger. With experienced N.C.O.'s and with so large a proportion of trained men the administrative sections have been efficient from the start (and their technical equipment, medical and nursing stores, and cookhouse requisites were available almost at once), while the new men rapidly grasped the principles of drill, stretcher duties, and first aid, aided by the examples and instructions of the veterans of France, Far East, and Russia.

At first the men, unless in possession of their old uniforms, wore civilian dress with brassards, but after technical stores were issued, uniform and necessaries were soon provided, and now all are complete down to cap badges and shoulder titles. To a large number of men the opportunity is welcome from their individual point of view, however much they must regret the general troubles which have led to the institution of the Force. Medical officers who served abroad have had a sad chance of realising how many of the old men whom they led in far-off campaigns have never been able to gain regular employment. Regular food, decent clothes, and freedom from worry about their families, even for a time, have done wonders for many of these men in the short time implied. But officers for the Force may be a difficulty. In many cases assiduous attention since their return has restored to practitioners their livelihood and removed the blight sustained in 1914 to 1919, but another absence, even short, might be serious; still less are they inclined to leave who have had to plant afresh. In consequence the Defence Force in some cases will be very short of medical officers. Under present circumstances local practitioners on a part-time basis are looking after the men of the battalions and in a large measure compensate for the deficiency; while in the medical units there is at present no call for the full staff, though lectures by medical men would supply finishing touches to the instructions of N.C.O.'s in nursing and first aid. In many units, however, a number of ex-Service officers who cannot at present see their way clear to leave their practices, pensions board, and other appointments, have registered their names as willing to be called up should any crisis develop, and no doubt have overhauled their uniform and their valises and made arrangements for neighbours to carry on their work should the call come. There are still vacancies, and any medical man able to register as willing to be called up if grave developments ensue should approach the nearest military depôt (Territorial or Regular) and make inquiries. If the unit approached does not require a medical officer they would direct him to the headquarters of the Assistant Director of Medical Services of the division or the nearest field ambulance, which would be able to give all particulars. His services might be utilised at first as civilian medical practitioner on a part-time basis attending the sick of a combatant unit in his neighbourhood.

Medical officers with previous service as such as a rule receive a temporary commission to the rank they received on retirement; those who have not previously served are gazetted as lieutenant. While employed they receive pay and allowances of their rank. Civil medical practitioners on a part-time basis are paid pro rata. At present recruiting, both of officers and men, is suspended, but future developments might lead to its reopening.

AUXILIARY ROYAL ARMY MEDICAL CORPS FUNDS.

The annual general meeting of the above Funds was held on April 29th at 11, Chandos-street, Cavendish-square, London, Sir John Goodwin in the chair. The hon. secretary, Sir William Hale-White, submitted the annual report, which showed that grants had been made in the benevolent branch to 27 widows and in the relief branch to 76 widows. The amount distributed in the benevolent branch was £1778 and in the relief branch £2613. Two new trustees were appointed, Col. Ewen Maclean and Mr. Martin Holt. The hon. treasurer submitted a satisfactory financial statement. £2064 was received in subscriptions and donations for the benevolent branch and interest amounted to £631; for the relief branch £2617 was received in subscriptions and donations and £815 from interest. Sir John Goodwin was re-elected President, Sir John Bland-Sutton was appointed to fill the vacancy among Vice-Presidents, and the following were elected members of the council: Col. W. H. Willcox, Col. C. R. Evans, Col. Donald Armour, Col. Joseph Griffiths. These Funds were instituted by Lieut.-Gen. Sir Alfred Keogh, G.C.B., late Director-General of the Army Medical Service, for the benefit of the orphans of the commissioned officers and the children of those severely disabled who served during the Great War and to give relief to the widows and orphans of the rank and file who were killed in action or died of wounds or illness contracted in the service of the three auxiliary branches of the R.A.M.C.

ROYAL NAVAL MEDICAL SERVICE.

Surg.-Lieut. A. McCallum is transferred to Royal Canadian Navy.

ROYAL ARMY MEDICAL CORPS.

To be temporary Majors: J. E. Bates and P. McK. Terry. To be temporary Captains: W. R Watt and E. E. Elliott. To be temporary Lieutenant: G. J. Scale.

Officers relinquishing their commissions:—Temp. Capt. (acting Major) A. G. Macdonald is granted the rank of Major. Temporary Captains retaining the rank of Captain: W. B. Gourlay and R. W. Collum. Temp. Hon. Capt. B. D. Brooker retains the honorary rank of Captain.

ARMY DENTAL CORPS.

Capt. T. K. Place, Dental Surgeon, late Special List, to be Captain.

DEFENCE FORCE.

To be temporary Majors: A. G. Reid, A. Robertson, and F. Ward. To be temporary Captains: W. A. Jackman, H. Mather, J. A. Mathers, G. M. Campbell, C. H. Vernon, K. Pretty, and H. G. Greaves.

2nd East Anglian Field Ambulance (D.F.).—To be temporary Major: S. J. Fielding.

1st (West Lancs.) Field Ambulance (D.F.).—To be temporary Major: F. W. B. Young.

1st (Highland) Field Ambulance (D.F.).—To be temporary Captain: F. M. Rorie.

3rd (Northumberland) Field Ambulance (D.F.).—To be temporary Lieutenant-Colonel: W. A. Thompson.

1st (West Riding) Field Ambulance (D.F.).—To be temporary Major: L. A. Mackenzie. To be temporary Captains: J. H. Blackburn, A. Ellison, W. S. Sykes, and A. A. Roberts.

TERRITORIAL FORCE.

Major G. B. Robinson to be D.A.D.M.S., 44th (Home Counties) Division.

Capt. E. A. Houchin resigns his commission, and is granted the rank of Lieutenant-Colonel.

Capt. T. A. Hindmarsh to be Major.

Capt. T. A. Hindmarsh (late R.A.M.C.) to be Captain.

ROYAL AIR FORCE.

C. A. E. I. Brownlee is granted a temporary commission as a Flight Lieutenant.

Capt. C. E. Lowe is transferred to the Unemployed List.

INDIAN MEDICAL SERVICE.

The King has approved the grant of the temporary rank of Major to Capt. J. Findlay whilst D.A.D.M.S.

Temporary Lieutenants to be temporary Captains: Vijaya Shankar Rao Pandit, Joti Prasad Rosha, Perry Prain Tabit, Mohan Lal Kalra, Jyoti Prasad Ganguly, Ramanath Singh, Chandres Charan Das Gupta, Sachindranath Chatterji, Gokal Chand Sood, Annada Persad Sinha, Laiq Chand Datt, Faiyaz Anwar Khan, Jotindra Mohan Banerjee, Ben Phillip Athaide, Prahlad Das Kapur, Kashinath Dattatraya Bhave, Raghunath Bapuji Khave, Sardari Lal Chopra, Narendra Nath Ray, Bhupes Chandra Das Gupta, Nilkanth Vinayak Pandit, Dattatraya Ganeshkotibhaskar, Narayandas Datta, Evelyn Samarasinghe, William Arthur Nason Chanmugam, Gamalathge Don Daniel Wijesekere, St. John Puvirajasinghe, Eric Stanley Brohier, Appu Hennedige Theodoré de Silva, Frederick Nicholas Jayewardene, John Edward Felix, John Oswald Perera, Edward Wilford Arndt, Vairamuttu Kathirgamatamby, Gour Lal Sen, Mysore Puttanna Sambamurti Rau, Mohamed Yacob, Bhupendra Nath Basu, Vaman Anant Belsare, Bajirao Moreshwar Vaidya, Satchit Kumar Sarkar, Joseph Sebastian Pinto, Dhirendra Nath Chakravarti, Beni Madhava Roy, Anantabandhu Roy Chowdhury, Madhav Krishna Kelavkar, Ardhachandra Banerjee, Ram Chand Mahajan, Balchandra Gangadhar Marathe (since resigned), Dodaballapur Hari Rau, Jagan Nath Piplani, Parmanand Harumal Jhangiani, Phanindra Mohan Lahiri, Tula Ram Birmani, Mangharam Rochiram Lelvani, Jamsetji Ruttonji Mirza, Bharron Dayal, Herbert McKenzie Strickland, Ardeshir Ratanji Wadhia, Pritam Varialsing Karamchandani, Shankar Rau Pandit, Cecil Gerald Sedgeley Corner (since deceased), Chinnamanoor Subbaroya Narayanswami Aiyar, Annada Charan Sen, Kakkadan Nandanath Krishnan, John Michael Pereira (since resigned), Charu Chandra Protihar, Harry Basil Rosair, Purushottam Gopal Gune, Amulya Dhan Sen Gupta, Jnanendranath Das Gupta, Neni Gopal Chandra, Ganapathi Sreekanta Kuppusamy Iyer, Jiwanda Ram Katariya, Paranji Ramchandra Rao, Kathira Vellu Muttu Kumaru.

DEATHS IN THE SERVICES.

Fleet-Surgeon Anthony Kidd, R.N. (retired), died on April 22nd, aged 62 years. He entered the Royal Navy in 1881, became staff-surgeon in 1893, and fleet-surgeon four years later. He saw considerable foreign service, chiefly in China, receiving the medal for service during the Boxer rebellion, in North America, and Bermuda. His last appointment was at Pembroke Dockyard, where he was from 1904 to 1914. In 1916 he went to Bath. He did valuable work at the Bath War Hospital and was also anæsthetist at the Bath Ear, Nose, and Throat Hospital.

GENERAL HOSPITAL, BIRMINGHAM.—At a meeting of the governors on May 6th Mr. H. Beckwith Whitehouse was elected honorary obstetric officer to the hospital, thus filling the vacancy caused by the retirement of Dr. Thomas Wilson on the conclusion of his term of office. Mr. Whitehouse has held the post of assistant obstetric officer and assistant clinical lecturer on diseases of women in the University of Birmingham. In 1913-14 he was Hunterian Professor in the Royal College of Surgeons and he has also been Ingleby lecturer at Birmingham.

Correspondence.

"Audi alteram partem."

SAFE CONDUCT OF LABOUR.

To the Editor of THE LANCET.

SIR,—Your leading article in THE LANCET for May 7th under this heading opens up no less important a subject than the total abolition of private practice in midwifery and in every grade of society as I shall attempt to show. The article, I assume, has been written by an obstetric surgeon attached to one of the large obstetric departments either in a special or general hospital and is engaged in actual midwifery private practice and incidentally earning his living, or at least adding to his income thereby. This hypothetical obstetrician goes through a long and arduous training until he reaches the goal of a position on the staff and then he does, or expects to do, what we all do—namely, begins to get a dividend on his investment. His dividend ranges from 40 to 100 guineas for a confinement. Mine averages a fraction over 2 guineas—it used to be a fraction over 1 guinea, the fraction being derived from the occasional 3 or 5-guinea case. If your leading article expresses the situation I should certainly be wiped out of existence as a practitioner of obstetrics in my private practice, as I make no secret of the fact that I cannot conduct a case of labour and make the necessary subsequent visits as well as the antecedent pelvimetry, &c., and with the necessary surgical ritual and sterile appliances incidental to a surgical operation, simply because my usual environment in a case of labour does not permit of it, and 2 guineas has its own limitations in purchasing capacity. But if I am to disappear as a private practitioner so should my more fortunate and perhaps capable colleague. We have both gained our experience on patients of the same social class, and I have no hesitation in asserting that we were no better when we started as students than I am in practising among the same social class in private as I gained my experience from as a student. Both of us, therefore, were as students the same potential sources of evil as I am to-day, and the only certain way to obviate this in the future is to prevent our homologous successors in the obstetric art from ever engaging in private obstetric practice, for there can be no certainty as to who will be a 40-guinea and who a 2-guinea man.

The assumption that I am such a danger to the community, as I infer from your leading article I am, has fortunately been made by the medical advisers of the Kent County Council, and doubtless by all other county councils as well, and steps have been taken to establish midwifery nurses throughout the county who are now attending a proportion of the midwifery cases formerly attended by medical practitioners and at a much lower figure than the exorbitant 2 guineas. This latter fee is only considered necessary in cases of obstetric emergency, requiring all the above-cited ritual and appliances necessary for a surgical operation, and is the amount offered to the general practitioner who consents to enrol himself to accept such fee when summoned by a maternity nurse in difficulties. As, however, the midwife is replacing the practitioner in normal labour the latter in time will have no experience of any form of labour other than what the midwife judges to be an abnormality. If this arrangement is going to improve the existing state of affairs I hope I shall not be here to experience the wholesale justifiable homicide of the general practitioner of my own generation.

The statement as to puerperal sepsis and deaths from the accidents of childbirth is certainly a great surprise to me, and it is in no pharisaical spirit that I say that I have never had either a case of puerperal sepsis or death of a mother at, or attributable to, childbirth during a period of 20 years' private general and midwifery practice, and there must be numbers of practitioners who can say the same. I have had most of the difficulties of labour and incomplete abortions to contend with under adverse environmental conditions, and before I wore gloves, and besides always having carried a boiler and thoroughly scrubbing my hands and the patient's vulva and buttocks with soap and water and corrosive, and never using anything to dry my hands or the patient with I have taken no other precautions. I was brought up on the douche for post-partum hæmorrhage as a student and extern assistant in the Rotunda, Dublin, but Leopold Landau and Strassmann in Berlin pretty effectually convinced me of its dangers. You state that "the morbidity of childbirth in private practice amounts to something like 15-20 per cent. of all cases." I am not sure that I know what the standard of morbidity is, and so my cases can never have been included in the "all." What verification have you of this statement, even assuming that everyone else knows the standard of morbidity? It seems a very bold assertion to make unless a big percentage of all confinements attended in England, say, can show at least a continuous twice daily temperature chart for ten days after confinement. "Meddlesome midwifery" is another expression that I think can be abused. Would, for instance, the turning of an occipito-posterior presentation into an anterior one, as I practise early in labour, and which, if I remember right, is advocated by Berkeley and Bonney in their midwifery, be regarded as meddlesome? The gentleman who lived up to "keeping his hands in his pockets" would most probably regard it as such.

If my practice is exceptional, and it does not differ in essentials from that of many men whom I have spoken to, the only alternative is the lying-in hospital for all cases, and that will gradually bring with it, in my opinion, the whole-time and State service, which I can see no alternative for in midwifery, if not in general practice altogether. One thing is certain, and that is that the public are demanding more and more freedom from pain in labour which almost necessitates the artificial termination of labour under anæsthesia in some form or other. Twilight sleep I have no experience of, but with the State hospital in being for all classes of patients it looks like becoming the routine treatment of normal and abnormal labour, supplemented, if necessary, by some other form of anæsthesia. The statement, "the incidence of septic infection in lying-in hospitals is extremely small" seems to me to contravert the alleged danger of vaginal examination; for operative procedure, such as forceps and version, &c., must be much commoner in such institutions than in private practice owing to the fact that actual and potential difficult cases are sent into hospital where vaginal manipulation becomes a necessity—unless Cæsarean section is going to replace all other procedure, as one would imagine from the practice of some specialists.

I am, Sir, yours faithfully,

Charing, Kent, May 9th, 1921. H. E. LITTLEDALE, M.D.

*** Our correspondent's deductions seem to us extreme. He is an experienced obstetrician, and so far from being eliminated, as he suggests, would become automatically the guide and counsellor to others less well equipped.—ED. L.

THE SEVEREST ANÆMIAS.

To the Editor of THE LANCET.

SIR,—The admirable summary of the difficulties of the above subject in an annotation in THE LANCET of May 7th and the attention now being given to the production of these anæmias by X rays impel me to draw your attention to an explanation published some ten years ago.[1] It was then suggested that pernicious anæmia, though of mixed intrinsic and extrinsic origin, is more intrinsic than extrinsic, and that the most satisfactory way of accounting for it is to regard it as a vice of development. The key to the situation consists in the recognition of the nature of development. Development is regarded as coincident with life and as divided into phases, first of progression, then of regression. It is, in short, best represented as a circular movement, which begins with the integration of the cell, continues with ever-increasing complexity and diminishing impetus up to middle age, and then merges into its declining or regressive phases, in which this process is reversed, until an ever-increasing simplification ends in the disintegration of death. This, at any rate, is the direction or tendency of the cycle, for the different organs differ so widely in the amplitude of their cycles that while one organ or one system of organs (e.g., the female reproductive organs) may practically run its course and be completed in about 35 years, another may not finish its revolution within double that period. Among these long-lived organs is the chromocytic. Its life-cycle is, indeed, so long or so slow that in the natural course of events it outlasts the cardio-vascular, and perhaps all other vital organs. But let us suppose that from any reason the cycle of the chromocytic organ is shortened, or hastened, so that the red marrow enters upon the last stages of its degeneration while other organs are still vigorous. It will begin, roughly speaking, to repeat the earlier stages of its developmental cycle.

Now these earlier stages are characterised by an abundant proliferation of embryonic cells. And when the cycle is so quickened that its senescent stages are anticipated, then again must we expect to meet with nucleated forms, with evidence of juvenility of the bone-marrow and of the manufacture of a copious supply of young cells. But these new cells are of no use, for they are not young, only spuriously young. They are in their second childhood, not embryonic but embryonoid, and are evidences of decrepitude. And being regressive and senile they cannot do the work of normal blood-discs, but can only pass on to their next phase of regression, which is molecular disintegration. As a matter of fact, they are useless, apart from their incompetence, if only for the reason that they are to all intents foreigners in the blood stream, and as the leucocytic organs are still comparatively young and vigorous they make short work of these nucleated strangers; indeed, they are equivalent to the blood-discs of some lower animals, as was long ago pointed out by Woods Hutchinson. They are therefore promptly destroyed, and the overgrowth of the spleen and the increased pigment in the liver and elsewhere are evidences of their wholesale slaughter.

As for the cause of this premature senescence of the red-blood organ, evidently anything which can unduly and profoundly accelerate its developmental cycle is a potential cause. Among such stimulants or irritants are some bacterial toxins. Arsenic, too, in its more intimate and potent forms has the same effect. But nothing seems better calculated to quicken the revolution of the cycle to its culmination in the breakdown of pernicious anæmia than the X rays. These, like arsenic, stimulate in small dose, irritate in large, and disintegrate if used still more excessively. They are capable of inducing senility of the skin and of the testes and ovaries, as well as senile disorders elsewhere, including pernicious anæmia and cancer. Probably even prolonged exposure to X rays would not cause pernicious anæmia were it not that there is already some inherent weakness or susceptibility of the bone-marrow. And nothing seems more likely to assist in the breakdown as some prior developmental incompetency. Such an inborn defect of development implies a short life-cycle and an undue readiness to undergo the changes of regression and senescence. It is especially in such circumstances that we account for the pernicious anæmia of early life, and, above all, for aplastic anæmia and for its peculiar features.

Apart from the way in which this theory fits in with and explains the phenomena of the severest anæmias there is plenty of evidence in its favour, some of which can be found in the book I have mentioned.

I am, Sir, yours faithfully,

Reading, May 8th, 1921. HASTINGS GILFORD.

RAT DESTRUCTION: A SUGGESTION.

To the Editor of THE LANCET.

SIR,—A recent voyage on a cargo steamer from Durban to Port Louis, Mauritius, has suggested the idea that vessels of this type might well prove to be very suitable for testing the efficacy of the Rodier method for rat destruction. In this method the rodents are trapped, the females killed, and the males set free. Males accordingly predominate in the long run, and the deficiency of females leads to a warfare of extermination amongst the males, the females also suffering in the strife. Many believe that this method is the best yet devised for reducing the numbers of rats, but it is difficult to obtain conclusive proof on the subject when the experiment is conducted under ordinary shore conditions.

On board a ship, however, it seems to me that valuable data could be collected. It is not difficult to ascertain with some degree of accuracy the normal average rat population of any vessel, though, it is true, this population varies, for, even if rats are prevented from boarding ships as free agents, many are conveyed aboard in cargo, especially in the case of merchantmen loading grain. Still, even taking into account this drawback, a cargo-carrier on a long voyage to Eastern ports would appear to offer special facilities for the investigation indicated, and I would suggest that the *Society for the Destruction of Vermin might* use its influence and see if anything can be done in this direction. If reliable statistics could be obtained from a ship-board experiment on a considerable scale they would be distinctly helpful to those entrusted with the duty of dealing with the rat menace either from an economic or a sanitary standpoint.

I am, Sir, yours faithfully,
ANDREW BALFOUR,
Director-in-Chief, Wellcome Bureau of Scientific Research.
Port Louis, Mauritius, April, 1921.

THE STATUS OF THE DISTRICT MEDICAL OFFICER OF HEALTH.

To the Editor of THE LANCET.

SIR,—In the correspondence columns of your issue of April 23rd a point was raised as to the relative official position of the county medical officer and the medical officer of health of a district within the county. To those outside the public health service it is commonly and erroneously accepted that as the county includes the district, so, in some similar kind of way, the county medical officer is superior to the medical officer of health of a district. The editorial note to Dr. Herbert Jones's letter (p. 879) in reference to this matter does not clear up the point at all, but rather confirms the error. It should be observed that by Art. 16 of the Sanitary Officers (Outside London) Order, dated Dec. 13th, 1910, the copy of the annual report which the medical officer of health of a district is required to transmit goes to the county *council* and *not to the county medical officer*. It is therefore properly to be addressed not to the latter, but to the clerk of the county council or to the chairman. In your expression "the county officer is suzerain to the district officer," the word "suzerain," which means "lord paramount," is certainly not applicable, for in the House of Commons on Nov. 18th last Dr. Addison, in reply to General Sir Ivor Phillips, stated quite frankly and definitely that a county medical officer of health did *not* supervise the district medical officer of health. There is, in fact, nothing in the whole of the statutory rules and orders relating to public health which gives the least support to this claim of "superiority."

I am, Sir, yours faithfully,
JAMES J. PATERSON, M.D.
Guildhall, Maidenhead, May 3rd, 1921.

*** Our correspondent differs from us only on a definition. The word "suzerain" implies no more than a nominal sovereignty over autonomous States, and we carefully qualified our expression with the words "to this extent."—ED. L.

SALICIN AS A REMEDY FOR RHEUMATISM.

To the Editor of THE LANCET.

SIR,—I understand that Buchner of Germany, Fontana and Rigotelli of Italy, and Le Roux of France, all claim as their work the first accurate investigation of the properties of salicin. In 1862, whilst surgeon in charge of H.M.S. wooden paddle-sloop *Salamander*, on surveying service in the coral sea off North Australia, I had a case of rheumatic fever; quinine had run out, and there was no drug store within a thousand miles. I happened to have a bottle of salicin, then hardly used in medicine, and not supplied by the Admiralty; I employed it with success, and may therefore fairly claim the discovery of the efficacy of the salicylic treatment of rheumatism.

I am, Sir, yours faithfully,
RICHARD CANNON, M.D.
Viña del Mor, Chili, March 20th, 1921.

A PROJECT OF GENERAL REPRESENTATION.

To the Editor of THE LANCET.

SIR,—On Saturday, May 28th, the annual dinner of the National Medical Union will be held at the Monico Restaurant, Piccadilly-circus, London, at 7.15 P.M. The price of tickets for admission will be 10*s.* 6*d.*, excluding wine. The London President of the Union, Dr. Alexander] Blackhall-Morison, will make a communication on "a project for the formation of a General Medical Council representative of the whole profession as a body, related on the one hand to the public and on the other to the government of the country and empire."

The Council of the Union invite all medical men to attend the dinner and hear the statement, which has received their approval as a practical scheme in the interests of both the public and the profession and one calculated to heal divisions in our ranks.

An early intimation to be present at the dinner will be welcomed and may be sent to either Dr. J. Wilson, 25, Larkhall-rise, Clapham, S.W.; Dr. A. Bousfield, *Tudor Lodge, Hornsey-lane, N.; or to myself at this* address.—I am, Sir, yours faithfully,
E. H. WORTH,
Hon. Secretary to the National Medical Union.
2, Aldrington-road, Streatham, S.W., May 8th, 1921.

THE HYGIENE OF THE SAILOR.

To the Editor of THE LANCET.

SIR,—Sixteen years ago I went for some voyages for my health as ship's surgeon, and in many instances can support Dr. Leonard Burton in his remarks in THE LANCET of May 7th under this heading. On being appointed to one of the newest ships of the Royal Mail S.S. Co. I drew their attention to the inadequacy of the hospital cabins and facilities for isolating cases of infectious disease. I drew up to scale plans for two four-berth hospital cabins, with bath-rooms and w.c.'s attached, and an attachment on the doors for connecting the Clayton apparatus for disinfection with SO_2. These cabins, together with a cabin for an attendant and one for myself for investigating materies, &c., to be on the raised poop deck aft, so that all infection should be left behind. I was not popular at first, but subsequently Sir Owen Phillips, with his capacity for seeing what was best for his ships, adopted my plans on all his new ships, with the result that for three and a half years I was able to prevent at once the spread of any infectious disease, of which I had to handle many varieties. In addition to these there were other hospital cabins with a very complete dispensary for'ard, besides one attached to my own consulting-room, and the company never hesitated to provide me with anything in reason. It is up to the doctor to insist on being provided with what is necessary, and if he does not do so he has himself to blame very often.

I am, Sir, yours faithfully,
REGINALD POLLARD, M.B., D.P.H., M.R.C.S.
Egerton-crescent, South Kensington, May 7th, 1921.

THE DIET OF THE WEANLING.

To the Editor of The Lancet.

Sir,—Work at infant clinics would lead to the view that the tendency at the present time to discourage giving milk in any quantity to the weanling is deplorable.

Anyone wishing to study the result in the children of the poor and less affluent middle-class should examine the five-year-olds about to start school. It has been my duty to do so for the last three years, and I have been appalled at their poor physique. The only bright spots have been usually in those cases where the children have had milk to drink. Rarely does one see a child of normal growth who is not getting milk. Indeed, to my mind, the one advantage of artificial feeding over breast-feeding is that the parents have been in the habit of buying milk for the baby and often keep it up; whereas the breast-fed baby gets a "bit of what we have ourselves," and little or no cow's milk. Certainly the worst cases of rickets that I have seen have been in breast-fed babies who have had no milk after weaning. At one time most babies got butter, now most babies get margarine made from vegetable oil, so have not even that protection. Given "food of a suitable kind," one might scrap the milk, but the point is so few get it, and incalculable harm may come from advising parents to do so (parents, moreover, who are not the least likely to overdo it). With regard to the children's dislike for it, one often sees an infant who will greedily suck a bottle full of milk with the greatest gusto, but refuses to take it from a cup or spoon. Is this dislike?

One might just as well say that the human mother had lost her function of lactation because she could not supply milk for butter as to argue that she has lost it because cow's milk is necessary for most babies.

I am, Sir, yours faithfully,

Leeds, May 9th, 1921. Marion E. Mackenzie.

THE DANGER OF ATHLETICS FOR GIRLS AND WOMEN.

To the Editor of The Lancet.

Sir,—Being one of those who maintained that women had a right to the vote and that their advice was most valuable and desirable on public matters, I also held, as most feminists do still, that sex was more or less incidental and that a well-trained woman could do anything a man could, unless, perhaps, when it was a case of exerting sheer physical force. I was a keen advocate of all forms of physical culture for girls, the more so as I suffered from neglect in that way myself as a child. Girls were encouraged by me to take up the work of a drill and games mistress, it appearing almost an ideal occupation. The more, however, I came in contact with women who had trained for it the more was I disappointed with the effect of that training upon them. The girls, also, who took up what had been regarded as boys' games, hockey, and even cricket, seemed to deteriorate. They seemed more selfish, more concentrated upon material things and material advantages. The girl of 15 appeared less a budding woman than an enlarged and accentuated copy of herself at 10 years old. She had not risen in the scale of being. There might be an affectation of being "sporting" about her, but actually the girl whose utmost achievement in physical work was to dance or perhaps to fence was quite as honourable and played the game of life at least as well.

But it was the grown women who made me decide finally against the present system of strenuous sports for girls and realise that the difference between men and women, boys and girls, was not one of education, environment, and opportunity, but was a vital and fundamental one. I knew many women who were physical experts and who prided themselves upon the fact. Few of them had not had at some time a more or less serious breakdown. I inquired into the after-careers of many and the results were not encouraging. This made me keep a very careful check on any girls I had to do with, though still I was most unwilling to acknowledge that girls could not do what boys could, forgetting that difference need not mean inferiority, but might even imply the opposite. Yet I saw that the young women joining in strenuous games became possessed of hard muscles, a set jaw, flat chest, and often a hard aggressive manner and an ungainly carriage. A girl's body is more elastic, more variable, and more easily altered than that of a boy. Nor should it be forgotten that the organs are more easily displaced. The attempt to make a boy of the girl has led to the cult of the "boyish" figure with undeveloped breasts. Broad elastic bandages are now worn round the chest to produce an unnatural flatness, while drugs are also taken, I am told, for the same purpose. It is unnecessary to say how dangerous are such practices, while a flat chest is really a deformity in a well-grown and developed young woman.

So much for their appearance. But the health of these athletic women is often more apparent than real. They frequently suffer from nerves (manifested in irritable tempers), from heart trouble, from some form of rheumatism, or from displacement of some kind. Sometimes the monthly disability that should prove them women stops for long periods. When there is any unaccustomed strain upon them they do not seem able to meet it. Their marriages are often childless, and I have many times heard, when a woman has lost a child or had a particularly difficult confinement surprise expressed. "She was such a fine strong girl," or "One would think an athletic girl such as she would be up and out almost at once, like a savage woman." I have been sorry to see the physical inferiority of children of sporting mothers, they often being nervous, and the mother becoming so as well sometimes. They compare badly with the stalwart sons many a slight feminine woman produced in Victorian days.

The attitude of these women to life is frequently not a normal one. Their mentality is not healthy. Many who decry marriage and affect to despise the opposite sex (while imitating them) are yet inordinately occupied with the discussion of sexual matters. Allied to this aspect is the curious influence exerted by some of these women on girls, neurotic girls seeming obsessed by them. Most of them seem to have stifled what is finest in woman—love, sympathy, tact, and intuitive understanding. When we object to girls joining in the games of boys we are answered that girls learn a lesson they much need—not to play selfishly for themselves, but to play for their side. I deny this. At adolescence girls are often almost dangerously altruistic, and a girl will exert herself far beyond her powers for her side, if not most carefully watched. She needs very delicate handling in her 'teens, for her feelings are subtle and elusive and her affections at full flood.

Unwillingly I have been convinced by the logic of experience. Strenuous games I believe bad for the woman and worse for the girl. And the sooner it is realised that the differences between the sexes are profound and vital and that these differences are accentuated and not lessened by evolution, the better for humanity. Let it be recognised that the present cult is a retrogression, and the young girl have placed before her the ideal of true womanhood, of all the qualities that make for motherhood; so that, whether she has her own family or finds happiness in some other sphere, she may realise it is her gift of "mothering" that makes her of value in the world.

I am, Sir, yours faithfully,

C. Cowdroy.

Crouch End High School and College, London, N.,
May 9th, 1921.

Bognor War Memorial Hospital.—In only two years this hospital has become a fully equipped institution, and already the provision of a new block is being talked about. One hundred and fifty-two patients were admitted during the year, and 67 operations were performed. The out-patients are constantly increasing; the number during the month of April this year was 222. The hospital is also becoming firmly established financially, and it is hoped to keep it free from debt. It is receiving good local support, and patients are invited to contribute to the cost of treatment. From this source £231 7*s*. has been obtained. It is hoped to provide wards for paying patients and a maternity ward in the future.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

The Dentists Bill.

THE Dentists Bill, which gives effect to the recommendations contained in the Report of the Departmental Committee on the Dentists Act, 1878, has now been printed. It is identical with the Bill which was introduced at the end of last session, except for a few alterations of minor importance for the purpose of meeting criticisms urged against the former measure, and a few other alterations of a purely drafting character. It is understood that the measure is now practically an agreed one. The Bill provides for the establishment of a Dental Board, consisting partly of dentists and partly of medical practitioners, together with a non-professional element. The first Board is to be entirely nominated, but in succeeding Boards 6 out of the 13 members will be elected by and from the dentists on the register. Clause 1 (which will take effect not earlier than one year or later than three years from the commencement of the Act) prohibits the practice of dentistry by unregistered dentists. Existing unregistered dentists are given the right of admission to the register, subject to evidence of good character, if they satisfy the Board that they have for five out of the seven years immediately preceding the commencement of the Act been engaged in the practice of dentistry as their principal means of livelihood. Existing unregistered dentists who have been in practice for less than five years will be required to pass an examination before being admitted to the register. The Board are given a dispensing power to deal with cases of persons who cannot meet the requirements of the Bill by reason of military service. Special provisions are included to deal with limited companies carrying on the business of dentistry. Existing rights are safeguarded, but in future all the directors and managers of such companies and the operating staff employed by them will be required to be registered dentists. The powers of the General Medical Council, so far as they relate to the maintenance of the Dentists Register, will be transferred to the Dental Board, but any regulations made by the Board under the Bill must be approved by the General Medical Council and the Privy Council.

HOUSE OF LORDS.

TUESDAY, MAY 10TH.

Public Health (Tuberculosis) Bill.

The Public Health (Tuberculosis) Bill was considered on Report and agreed to.

HOUSE OF COMMONS.

WEDNESDAY, MAY 4TH.

Internment of a Heart Disease Patient.

Mr. MYERS asked the Chief Secretary to the Lord Lieutenant of Ireland whether his attention had been drawn to the case of Frederick Schweppe, who was arrested on Good Friday morning and was still imprisoned at Arbour Hill; whether he was aware that on Nov. 29th, shortly after a period of treatment for valvular disease of the heart at the Mater Hospital, Mr. Schweppe was arrested and detained until Dec. 7th, when he was discharged, the military doctor at Arbour Hill having certified that he was a very bad case and not fit for internment and ought to be released immediately; that from then until Good Friday Mr. Schweppe attended the doctor; that when he was arrested on Good Friday he was roughly handled by men of the auxiliaries; that he was at present suffering from sleeplessness and his health was generally very weak; that Dr. F. H. Moore, of the Mater Hospital, had certified that Schweppe had been attending the dispensary for months past and been treated for serious and apparently progressive heart disease; and whether, in view of the fact that nothing of an incriminating nature was found in Mr. Schweppe's house, and in view also of the man's state of health as certified previously by the military doctor of Arbour Hill, he would give instructions for his immediate release.—Sir H. GREENWOOD replied: In the workshop in rear of the house occupied by this man a number of revolvers and automatic pistols were found, in addition to explosives and detonators, and there was good ground for believing that he was concerned in the distribution of these munitions. An internment order has been made against him, but he is at present in hospital suffering from dilated heart and hernia, and not in Arbour Hill as stated. It is true that he was previously arrested on Nov. 29th, but there is no record of any such medical certificate as is referred to in the question. No allegation that he was ill-treated on arrest has previously been brought to my notice, but I will have inquiries made. Careful attention will be paid to this man's health, and he will not be transferred to an internment camp unless he is fitted for such transfer; but in view of the circumstances in which he was arrested I am not prepared to order his release.

War Casualty Return.

Sir WILLIAM DAVISON asked the Prime Minister if he would state what were the total casualties in killed and wounded suffered by Great Britain, the Dominions, by each of the Allies, and by Germany during the late war.—Mr. CHAMBERLAIN (Leader of the House) circulated the following printed return:—

Return Showing Approximate Casualties Suffered by Great Britain, India, the Dominions, by each of the Allies, America, and Germany During the late War.

Country.	Deaths from all causes.			Wounded.			Total deaths and wounded.			—

Turkey	—	—	300,000	—	—	570,000	—	—	870,000	..

Note.—The figures given in this Return include British naval casualties between August 4th, 1914, and Nov. 11th, 1918, and British military casualties during the period August 4th, 1914, to April 30th, 1920, and excludes casualties to Chinese Labour Corps recruits locally in Salonica and Mesopotamia, and camp followers in East Africa.

Note.—The figures in regard to Bulgaria were furnished by the Bulgarian General Staff in 1919, and were considered by them under-estimate, as many archives were lost in the debacle of 1918.

Report of Committee on Dangerous Drugs.

Mr. GILBERT asked the Secretary for the Home Department when the Report of the Committee on the Regulations under The Dangerous Drugs Act, 1920, might be expected; and whether, and when, it would be published.—Mr. SHORTT replied: The Committee have, I understand, nearly completed their inquiry, but I hope to have their Report shortly. The Report will be published.

Finance of Voluntary Hospitals.

Mr. GILBERT asked the Minister of Health when the report of the Departmental Committee on the finances of the voluntary hospitals might be expected; and whether and when it would be published.—Sir ALFRED MOND replied: I am informed that the Committee will finish hearing evidence this week, and hope to be in a position to present their report by the end of the month.

Military and Naval Cases of Small-pox.

Mr. RAFFAN asked the Minister of Health in which hospitals the four naval and 13 military cases of small-pox, which were reported in 1919, were treated.—Sir ALFRED MOND replied: The names of the hospitals and the number of cases treated in each are as follows: Colchester Borough Small-pox Hospital (1); Evan Fraser Hospital, Hull (3); Falking Grange Hospital (1); Lincoln City Small-pox Hospital (2); Liverpool Port Sanitary Hospital (2); Military Hospital, Cambridge (1); Military Hospital, Nell-lane, Manchester (1); Prees Heath Military Hospital (2); Royal Naval Hospital, Portsmouth (1); 3rd London General Hospital (1); West Suffolk County Hospital (1). One of the military cases was not removed to hospital.

Treatment of Probationer Nurses.

Mr. DENNIS HERBERT asked the Minister of Health if his attention had been called to the alleged unfair treatment of probationer nurses at the West Middlesex Hospital, under the Brentford Board of Guardians; if he was aware of the serious discontent thus caused amongst the nursing staff; and what steps he proposed to take in the matter.—Sir ALFRED MOND replied: I have been in communication both with the board of guardians and with various associations which have taken this matter up on behalf of the nursing staff, and I have offered, if they so desire, to arrange a meeting between these associations and officers of my Department, at which the case can be further considered in the light of the explanation which I have received from the guardians.

Diagnosis and Treatment of Venereal Disease.

Mr. WATERSON asked the Minister of Health whether he could produce any evidence to show to what extent cures were being effected as a consequence of the large expenditure of public money which was now taking place in connexion with the diagnosis and treatment of venereal diseases; and, if so, would he arrange for such evidence to appear in the annual reports of his department.—Sir ALFRED MOND replied: The value of the work done at venereal disease centres cannot be measured solely on the basis of the proportion of cures effected. I am advised that in the case of these diseases prolonged treatment followed by a period of observation is frequently necessary before a cure can be pronounced, and in some cases it is difficult to arrive at a conclusion as to cure. There are, however, many cases which, although they fail to continue treatment or to remain under observation until a cure can be pronounced, are nevertheless rendered non-infective before ceasing attendance at the clinic. As the honourable Member is aware, the system of clinics has not been long in operation. The results are under careful observation, and the report of the chief medical officer of the Ministry for this year will contain a statement on the subject.

THURSDAY, MAY 5TH.

Appeal Tribunals.

Replying to questions by Mr. HURD and Captain FOXCROFT regarding the expediting of the work of the Pension Appeal Tribunals, Captain H. D. KING (for the Lord Chancellor) stated that five additional Pension Appeal Tribunals would commence to sit this month, and further tribunals were in course of formation. The average period which elapsed between the date an appeal was received by the Pensions Appeal Tribunals and the date it was heard was at present 10 weeks. In Somerset all appeals received up to the beginning of February last had been dealt with or would be heard within the next two weeks.

Treatment of Shell Shock.

Mr. HURD asked the Minister of Pensions what special arrangements were made for ex-soldiers who were suffering from shell shock and were detained in public asylums; how their treatment was differentiated from that of ordinary inmates; and what steps were taken, or were in contemplation, for treatment especially suited to their malady, and for independent examination at intervals by military doctors with a view to their earliest possible recovery.—Mr. JAMES PARKER replied: Ex-Service men are not medically treated in public asylums unless certified under the Lunacy Acts to be insane. Men suffering only from shell shock are not so certified. Treatment is in such cases provided in an institution of the Ministry of Pensions, the men being under the care of experienced medical officers who have special knowledge of the particular disability and of the appropriate treatment.—Mr. HURD: Is it not a fact that ex-soldiers in these public asylums are treated as though they were ordinary lunatics, and is that not a state of things that ought to be changed?—Mr. PARKER: I do not think that is true, but I cannot speak with authority on the matter.—Mr. HURD: Will the honourable gentleman raise this question with the Minister so that a specific answer to the question may be obtained?—Mr. PARKER: Certainly.

Unemployment and Sickness Benefit.

Sir WALTER DE FRECE asked the Minister of Labour whether his attention had been called to the fact that during the time an insured person was in receipt of unemployment benefit his health card was not stamped and he was consequently falling into arrears with his contributions under this section; whether unless such arrears were paid up his sickness benefit would be reduced accordingly; whether under sickness benefit the contrary practice was observed; and whether the practice in the two cases could be made identical.—Sir A. MOND (Minister of Health) replied: It is the case that during periods of unemployment insured persons fall into arrears in respect of their health insurance contributions. There is, however, an allowance of four weeks of unemployment in any year before any penalty is imposed in the form of reduction of sickness benefit, and even if the arrears exceed this amount no reduction in sickness benefit can take place until the following year, and this reduction can be avoided by the payment of a comparatively trifling sum in the autumn preceding. Although the scheme of unemployment insurance differs materially from that of health insurance, it is not the case, as the honourable Member would appear to think, that an insured person is credited with a contribution for unemployment insurance in respect of any week for which he received sickness benefit.

Indian Medical Service Statistics.

Major GLYN asked the Secretary for India what was the present total establishment of the Indian Medical Service; what proportion of the officers in that Service were British born or natives of India in the following years: 1910, 1914, 1918, and 1921; what steps were being taken to safeguard the position of British-born officers in that Service who joined before the war; what steps, if any, were being taken to encourage British-born students to enter the Indian Medical Service; and what were the proportions of candidates to enter the Service, British and Indian, in 1910, 1914, 1918, and 1920.—Mr. MONTAGU replied: The number of officers holding permanent commissions in the Indian Medical Service on Jan. 1st, 1921, was 767. The following table gives the numbers of permanent officers in the Indian Medical Service on Jan. 1st, 1910, 1914, 1918, and 1921:—

	British born.	Indians.	Total.
1910	694	37	731
1914	722	48	770
1918	712	71	783
1921	638	129	767

The distribution as between British born officers and Indians has been arrived at after an examination of the names in the Army list and must therefore be regarded as only approximately correct. I am not sure that I understand what is meant by that part of the question regarding British born officers who joined the Service before the war. The position of such officers is in no way jeopardised by the admission of officers, European or Indian, during the war. Every effort is being made to fill up existing vacancies available for Europeans, and the conditions as regards pay, leave, and pension have recently be considerably improved. I am advised, however, in view of the great shortage of medical men caused by the war, that it will be a year before the medical schools of this country are in a position to turn out qualified men of the standard required for the Service in anything like the normal numbers. The following are the numbers of candidates who entered the Service in 1910, 1914, 1918, and 1920:—

	Europeans.	Indians.	Total.
1910 (Examination) ...	22	6	28
1914 (Examination) ...	18	15	33
1918 (Selection)	9	9	18
1920 (Selection)	23	52	75

Dentists Bill.

Sir A. MOND presented a Bill "to amend the Dentists Act, 1878, and the provisions of the Medical Act, 1886, amending that Act." The Bill was read a first time and ordered to be printed.

MONDAY, MAY 9TH.

The Bastardy Bill.

Captain BOWYER asked the Prime Minister whether he was aware of the great volume of support that existed in the country for the Bastardy Bill; whether he realised that the Bill was identical in its clauses with the Bill which left the Standing Committee last session; and whether, in view of its simplicity and of the urgent needs of its reforms, he would facilitate the passage of the Bill into law.—Mr. LLOYD GEORGE replied: It is premature until we see what time is available at the end of the session to make any fresh promises as to the allocation of the time of the House.

The Necessity of Cheap Milk.

Captain Viscount CURZON asked the President of the Board of Trade whether he was aware that the price of milk in the Metropolitan area had been fixed at 8*d*. per quart for the summer months; and whether, in view of the vital necessity of cheap milk to the working population, he would immediately appoint a committee to inquire into and report on the cost of production and distribution with the view to determining what was a fair price to the consumer.—Sir W. MITCHELL-THOMSON (Parliamentary Secretary to the Board of Trade) replied: I understand that the price of 8*d*. is that recommended by the National Federation of Dairymen's Associations. The retail price of milk depends not only on the cost of production and distribution of such milk as is consumed directly, but also upon the loss which has to be incurred by the conversion of large quantities of milk at this season into butter and cheese, the prices of which are governed by those of imported supplies. The report on milk prepared by the subcommittee appointed by the Standing Committee on Trusts (Cmd. 1102) indicated that combinations of distributors had not dealt unfairly with either producer or consumer down to the autumn of last year, and I see no reason to think that circumstances are different at the present time. To reimpose control of milk prices would involve the re-engagement of a considerable and costly staff, and it is not clear that the consumer would ultimately benefit.

Medical Students and Defence Force.

Mr. BRIANT asked the Secretary for War if, as many members of the Defence Corps were being retained with no special duties to perform who left their medical and other studies in order to meet a national emergency, consideration would be given to application for leave on the undertaking that they would immediately rejoin if their services were required.—Lieutenant-Colonel Sir R. A. SANDERS (Under Secretary for War) replied: Instructions have already been issued authorising officers commanding units to grant leave to soldiers of the Defence Force up to a maximum of 10 per cent. of a unit at any one time. These instructions provide for preference being given to cases of hardship, including teachers, students, apprentices, and those undergoing training under the Board of Education and Ministry of Labour, especially those about to undergo examination, and those employed in one-man businesses or in similar positions, the remainder being chosen by ballot.

Appointments.

Successful applicants for vacancies, Secretaries of Public Institutions, and others possessing information suitable for this column, are invited to forward to THE LANCET *Office, directed to the Sub-Editor, not later than 9 o'clock on the Thursday morning of each week, such information for gratuitous publication.*

BULLEN, H., F.R.C.S., has been appointed head of the Department of Orthopædics, including Remedial Exercises and Massage, at Charing Cross Hospital.

CORBETT, W. V., M.R.C.S., L.R.C.P., Pathologist to the London Lock Hospital.

FISHER, A. G. T., M.C., F.R.C.S., Assistant Surgeon to the Seamen's (Dreadnought) Hospital, Greenwich.

HERBERT, J. F. J., M.B., B.Ch., First Assistant Medical Officer to the Marylebone Infirmary.

Royal Alexandra Hospital for Sick Children, Brighton: EDMONDS, FLORENCE M., M.D., B.S. Lond., Honorary Physician: FITZMAURICE-KELLY, M., M.B., B.S. Lond., Honorary Assistant Surgeon.

Vacancies.

For further information refer to the advertisement columns.

Adelaide University.—Professor of Zoology. £1100.
Barrow-in-Furness County Borough.—Asst. Sch. M.O. £500.
Bath, Royal Mineral Water Hospital.—Res. M.O. £250.
Bedford County Hospital.—Asst. H.S. £150.
Birmingham, Queen's Hospital.—Hon. Obst. O.
Bootle Borough Hospital.—H.S. £150. Also Hon. S.
Cardiff City and Port Education Authority.—M.O.H. and Chief M.O. £1200.
Cardiff, King Edward VII. Welsh National Memorial Association.—Asst. Tuberc. P. £300.
Cardiff, King Edward VII. Hospital.—H.S. £200.
Cardiff, University College of South Wales and Monmouthshire, Welsh National School of Medicine.—Prof. of Med. and Prof. of Surg. £1500 each.
Chester Royal Infirmary.—Asst. H.S. £175.
Colchester, Essex County Hospital.—H.S. £200.
Dublin University.—Chair of Zoology. £800.
Dumfries, Crichton Royal Mental Hospital.—Clin. Path. £400.
Dundee Royal Infirmary.—Hon. Asst. Gynæcol. and Obstet. Dept.
East Sussex County Council Education Committee.—Asst. Sch. M.O. £500.
Exeter, Royal Devon and Exeter Hospital.—Hon. Asst. S. and Hon. Surg. Reg.
General Post Office, Headquarters Medical Department.—Asst. M.O. £300.
Great Northern Central Hospital, Holloway, N.—H.S. £150.
Harrogate Infirmary.—H.S. £150.
Hellingly, East Sussex County Mental Hospital.—Sec. Asst. M.O. £450.
Hospital for Sick Children, Great Ormond-street, W.C.—Radiographer. Also Clin. Asst. in Venereal Dept. £1 1s. per visit. H.S. £100.
Hull Royal Infirmary.—Asst. H.S. £150.
Ipswich, East Suffolk and Ipswich Hospital.—H.P.
Kingussie, N.B., Grampian Sanatorium.—Locum.
London Temperance Hospital, Hampstead-road, N.W.—Ophth. S. and Asst. S. Also Res Cas. O. £125.
Manchester Royal Infirmary.—Res. Surg. O. £250.
Manchester, St. Mary's Hospitals for Women and Children.—Asst. M.O. £100.
Manchester, Whitworth Park Hospital.—H.S. £100.
Metropolitan Asylums Board Tuberculosis Service.—Jun. Asst. M.O. at High Wood, Brentwood, Essex. £515 6s.
Middlesbrough Education Committee.—Asst. School M.O. (Female). £500.
Miller General Hospital for South-East London, Greenwich-road, S.E.—Res. Cas. O. £150.
National Hospital for the Paralysed and Epileptic, Queen-square, Bloomsbury, W.C.—Res. M.O. £200.
Nottingham City Education Committee.—Jun. Asst. Sch. M.O. £537 10s.
Orkney, Eday Parish Council.—M.O. £5 per week.
Preston and County of Lancaster Royal Infirmary.—H.S. £200.
Prince of Wales's General Hospital, Tottenham, N.—Hon. P. and Hon. Asst. P.
Queen Mary's Hospital for East End, Stratford, E.—Cas. O.
Rochdale Infirmary and Dispensary.—Jun. H.S. £200.
Royal College of Surgeons of England.—Election to Court of Examiners. Also Election of Professors and Lecturers.
Royal Naval Dental Service.—Appointments.
Royal Naval Medical Service.—Surg.-Lieuts. 26s 6d. per diem.
Royal Waterloo Hospital for Children and Women, S.E.—Hon. P. and Hon. Gynæcol.
St. Bartholomew's Hospital.—Asst. M.O.'s to X Ray Dept.
S. George's Home, Milman's-street, Chelsea, S.W.—Part-time Visit. Asst. M.O. £200.
Scottish Board of Health.—Part-time Local Referees. £2 2s. per session.
Sheffield City.—Asst. Tuberc. O. £350.
South London Hospital for Women, South Side, Clapham Common, S.W.—Temp. (Female) Asst. S.
South Shields County Borough.—Ven. Dis. M.O. £750.
Staffordshire General Infirmary.—H.S. £250.
Swinton and Pendlebury Urban District.—M.O.H. and Sch. M.O. £800.
Taunton and Somerset Hospital.—Sen. and Jun. H.S.'s. £200 and £150.
Weir Hospital, Grove-road, Balham, S.W.—Res. M.O. £200.
Worcester County and City Mental Hospital, Powick.—Sen. Asst. M.O. £450 Also Jun. Asst. M.O. £350.
York County Hospital.—Third Res. O. £150.

Births, Marriages, and Deaths.

BIRTHS.

FARR.—On May 3rd, at Pembroke-road, Kensington, W., the wife of Dr. Arthur Farr, of a son, prematurely (lived for a few hours).

MILTON.—On May 5th, at "High Lea," Hendon, the wife of Wallis Milton, L.D.S.R.C.S. Eng., of a son.

MARRIAGES.

MOLLAN—DES VŒUX.—On April 7th, at Christ Church, Rawalpindi, India, Captain Mollan, M.C., R.A.M.C., to Violet Samana, youngest daughter of the late Lieutenant-General Sir Charles Hamilton Des Vœux and Lady Des Vœux, Palace Mansions, Kensington, W.

WILSON—BOYD.—On May 3rd, at Glasgow, Kenneth John Talbot Wilson, M.B., Ch.B., of Blandford, Dorsetshire, to Agnes Mitchell, second daughter of Mr. David M. Boyd, of Giffnock, Glasgow.

DEATHS.

BROGDEN.—On May 4th, suddenly, at Ashdown Lodge, Bathurst-road, Folkestone, Richard William Brogden, M.B., B.S., aged 6[illegible]

HOLLINGS.—On May 3rd, at Gordon-street, W.C., Edwin Hollings, M.D., in his 79th year.

HOYSTED.—On May 3rd, at Geeta, Sidcup, Kent, Isaac Hoysted, Colonel, R.A.M.C., retired, aged 83.

LONGSTAFF.—On May 7th, at Putney, George Blundell Longstaff, M.A., M.D.Oxon., F.R.C.P., F.S.A., F.L.S., F.G.S., in his 73rd year.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages and Deaths.

Medical News.

UNIVERSITY OF CAMBRIDGE.—At the congregation held on May 7th the following degrees were conferred:—

M.D.—A. T. Edwards, St. John's.
M.B. and B.Ch.—J. B. Hunter, St. John's; W. E. H. Banks, Clare; H. Gainsborough, Downing.
M.B.—H. A. Whyte-Venables, Queen's.
B.Ch.—W. N. Goldschmidt, Pembroke.

UNIVERSITY OF OXFORD: *Wilde Readership in Mental Philosophy.*—The electors to this readership will shortly proceed to the election of a reader. The emoluments of the readership amount at present to £400 a year. Candidates are requested to send in their applications, with evidence of their qualifications, to reach the registrar of the University not later than June 1st, 1921. An extract from the regulations is published in the University Gazette (Clarendon Press), April 21st.

Diploma in Public Health.—The Board of the Faculty of Medicine has issued the new syllabus of examination, which will come into force in Michaelmus term, 1921. The examination in "General Pathology with Special Relation to Infectious Diseases" (paper, practical work, and viva voce) is transferred to Part I.; a practical and viva voce examination in pathology and bacteriology is retained in Part II.

Rolleston Memorial Prize, 1922.—The next award of this prize, which is of the value of about £100, will be made in the summer term of 1922. The prize is awarded for original research in any subject comprised in the following list: animal and vegetable morphology, physiology and pathology, anthropology. Candidates must forward their memoirs to the registrar before March 31st, 1922. The conditions of eligibility are published in the University Gazette of April 27th.

UNIVERSITY OF LONDON.—A course of eight lectures on Metabolism of Cholesterol and the Sterols will be given by Mr. J. A. Gardner at the London (R.F.H.) School of Medicine for Women (8, Hunter-street, Brunswick-square, London, W.C.), at 5 P.M. on Tuesdays, beginning on May 17th.—A course of eight lectures on Experimental Studies in Vegetable Physiology and Vegetable Electricity will be given by Professor A. D. Waller, F.R.S., and Mr. J. C. Waller in the Physiological Laboratory of the University, South Kensington, London, S.W., at 5.15 P.M. on Wednesdays, beginning on May 18th. Attendance at the courses is recognised in connexion with the B.Sc. (honours) degree in physiology.—A course of four lectures on the Interpretation of the Structure of the Brain is now being given in the Department of Anatomy, University College, Gower-street, W.C., by Dr. C. U. Ariens Kappers (Director of the Central Institute for Brain Research, Amsterdam) at 5 P.M. The first took place on May 13th, and the other lectures are being held to-day, Friday, and on May 19th and 20th. All these courses of lectures are addressed to advanced students of the University and to others interested in the subjects. Admission is free, without ticket.

UNIVERSITY OF MANCHESTER.—At a meeting of the governors of the University Court on May 4th Sir H. Miers, the Vice-Chancellor, reviewing the work during the past half year, stated that the number of students was 2895, including 508 at the College of Technology, 654 women, and 9000 ex-Service students. He said that in carrying out ordinary duties the University was faced by a large annual deficit. The appeal fund had so far only yielded £220,000, a sum far short of the half-million asked for. A good lead had been given by Oldham (£8353) and Stalybridge (£3607). Some of the grants from local authorities had been increased. Comparing the responses at Liverpool with those at Manchester, the Vice-Chancellor said that Manchester had been badly beaten by Liverpool, whose appeal fund had reached £300,000. It was resolved to confer the honorary degree of D.Sc. on Professor C. S. Sherrington.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—Licences to practise Physic have been granted to the following candidates:—

*Dulcie S. Adkins, Royal Free; Samuel E. Amos, St. Thomas's; Lyon H. Appleby, London; George Armitage, Leeds; Frederick Back, St. Thomas's; Edward T. Bailey, Middlesex; Francis G. L. Barnes, St. Bart.'s; Geoffrey M. F. Barnett, New Zealand and Middlesex; Sydney H. Barnett, Cambridge and St. Thomas's, Davis E. Bedford, Middlesex; Kaikhushroo Maneckji Bharucha, Bombay and London; Frank A. Bryning, King's College; *Mary Barfield, St. Mary's; Samuel B. Chambers, Charing Cross; Philippe Conacaud, Guy's; Frederick C. Cozens, Cambridge and St. Bart.'s; Herbert A. Crowther, Cambridge and Guy's; Carl K. Cullen, London; Charles R. Dansie, King's College; Fernand Edouard Camille Deveney, Geneva; Irving G. de Zilva, Madras; Charles F. T. East, Oxford and King's Coll.; *Keridwen St. Valentine Edwards, Cardiff and Univ. Coll.; Guy W. Elkington, Guy's; Ralph W. Fairfax, Charing Cross; Sadik Farris, Liverpool; *Katherine M. L. Gamgee and Arthur J. Gardham, and *Janet K. Gatty, Univ. Coll.; Werner Göthe, Middlesex; John B. Gregor, Guy's; Simon Grossman, Edinburgh and Middlesex; Alan B. Hacking, Middlesex; William B. Hargreaves, Manchester; *Eleanor Harse, Royal Free; William E. Hayes, Oxford and St. Bart.'s; Strafford S. Hewitt, St. Mary's; Joseph W. Hirst, Cambridge and King's Coll.; Reginald W. P. Hosford, St. Bart.'s; *Margaret O. Howell, Cardiff and Univ. Coll.; Bryan L. Jeaffreson, St. Bart.'s; William D. Jenkins, Middlesex; David E. Jones, Cardiff and St. Bart.'s; James T. Jones, Guy's; Mohammed Kamil, Middlesex; George W. Karunaratna, Cambridge and Middlesex; *Mary E. Kennedy, Cambridge and London; Morris Korn, London; John H. Le Brasseur, Cambridge and St. Bart.'s; Robert Lee-Michell, McGill and Middlesex; *Bessie Levin, Univ. Coll.; Charles G. Lewis, Birmingham and Univ. Coll.; Edmund O. Lewis, Cambridge and Univ. Coll.; William B. A. Lewis, Cambridge and St. Bart.'s; Evan T. Lloyd, Guy's; John R. Lund, Cambridge and St. Thomas's; Christopher H. Macklin, Middlesex; *Dorothy McNair, Royal Free; *Henrietta A. C. Main, St. Mary's; Sytze E. J. Miedema, Amsterdam and St. Bart.'s; *Sybil G. Mocatta, St. Mary's; John C. R. Morgan, Westminster; Bertram S. Nissé, London; Geoffrey Noott, Guy's; Montague M. Ostrowick, Edinburgh; Rupert J. Parry, Univ. Coll.; Eric F. Peck, Liverpool and St. Bart.'s; Frederick A. Phillipps, St. Thomas's; *Marjorie Pierce and *Cassie Ethel Pratt, Royal Free; William S. Ratnavale, Calcutta and London; Howard L. Rayner, Oxford and King's Coll.; Andrew McKie Reid, Liverpool; John Reith, Oregon and Univ. Coll.; *Edith M. Rooke, Royal Free; Frederick M. Rossiter, Michigan, Rush, Penn., and Univ. Coll.; Charles I. Schiff, London; Carl G. Schoneboom, Groningen and St. Bart.'s; *Margaret Scott-Moncrieff, Univ. Coll.; George Selvaratnam Sinnatamby, Ceylon; Henry L. Slaughter, St. Thomas's; *Elfrida E. A. Spencer, Charing Cross; Harold E. Suter, St. Mary's; Edward Tagoe, Cambridge and Univ. Coll.; Harold B. Taylor, St. Mary's; Horace W. Taylor, Manchester; Clement P. Thomas, Westminster; Eric W. C. Thomas, St. Bart.'s; Bernard W. Thompson, Cambridge and St. Bart.'s; Frederick H. W. Tozer and John P. Traylen, London; Frances I. G. Tweedie, Cambridge and St. Thomas's; William G. D. H. Urwick, St. Bart.'s; *Mary G. Vaughan, King's Coll.; Horace S. Ward, Leeds; *Mildred Warde and Joan M. R. Warwick, Royal Free; Joseph F. Weakley, Univ. Coll.; Robert A. Webb, Johns Hopkins and Middlesex; *Agnes E. Westwood, St. Mary's; Henry L. Willey, Cambridge and St. Thomas's; David C. Williams, London; and *Constance M. Willis, St. Mary's.

* Under the Medical Act, 1876.

LITERARY INTELLIGENCE.—Messrs. William Hodge and Co. will shortly publish in the well-known series of Notable British Trials a volume dealing with the case of Burke and Hare, edited by Mr. William Loughead.

LONDON HOSPITAL MEDICAL COLLEGE.—The Schorstein memorial lecture will be delivered by Dr. A. G. Gibson on Friday, June 3rd, at 4 P.M., in the anatomical theatre of the College. The subject will be Chronic Inflammatory Diseases of the Spleen. Members of the profession are invited to attend.

ROYAL INSTITUTION.—A general meeting of the members of the Royal Institution was held on May 9th, Sir James Crichton-Browne, treasurer and vice-president, in the chair. Sir J. J. Thomson was elected honorary professor of natural philosophy, and Sir Ernest Rutherford professor of natural philosophy. The Friday evening discourse on May 20th will be delivered by Professor E. H. Starling, F.R.S., on the Law of the Heart.

QUEEN'S HOSPITAL FOR CHILDREN.—A course of post-graduate lectures, free to practitioners and students of medicine, has been arranged for May and June and will be held in the board room of the hospital, Hackney-road, Bethnal Green, London, E. The first lecture will be given on Thursday, May 19th, at 4 P.M., by Mr. B. Whitchurch Howell, the subject being the Principles of Orthopædic Surgery (illustrated by cases). Subsequent lectures will be announced in our Medical Diary.

FEDERATION OF MEDICAL AND ALLIED SOCIETIES.—A large number of acceptances have been received for the annual dinner of the Federation at the Café Royal on Thursday, May 26th. Dr. Addison, the first Minister of Health, and his successor, Sir Alfred Mond, have both accepted invitations to be present. As Monday, May 23rd, is the last day on which applications for tickets, price 12*s.* 6*d.*, exclusive of wine, can be received, members of the medical profession are asked to make early application, stating whether they wish to bring any guests and enclosing a remittance.

DONATIONS AND BEQUESTS.—Sir John O. S. Thursby, of Burnley, left £5000 to the Burnley District Nursing Association and £2500 to the Victoria Hospital, Burnley.—Under the will of the late Mrs. Julia Norman, of Brunswick-terrace, Hove, who has left an estate of the value of £36,147, with net personalty £17,396, the testatrix divides the bulk of her property between the Putney Hospital, Lower Common, Putney, and the Royal Hospital for Incurables, Putney Heath.

GENERAL MEDICAL COUNCIL.—The summer session of the Council will commence at 2 P.M. on Tuesday, May 24th, when the President, Sir Donald MacAlister, will take the chair and give an address. The Council will continue to sit from day to day until the termination of its business.

MEDICAL SOCIETY OF LONDON.—Lord Dawson of Penn will deliver the annual oration on Monday, May 23rd, at 9 P.M., on "The Colon and Colitis." A conversazione will follow the oration.

ABERDEEN UNIVERSITY CLUB, LONDON—The bi-annual dinner of the club is to be held on Thursday, May 19th, at 7.30 P.M., at the Criterion Restaurant, Professor J. A. MacWilliam in the chair. The secretary, Dr. W. A. Milligan, 11, Upper Brook-street, W. 1, will be glad to hear from any Aberdeen graduates who would like to be present.

LIVERPOOL MEDICAL INSTITUTION WAR MEMORIAL. On May 11th the Bishop of Liverpool unveiled a tablet, the gift of the ex-President, Mr. W. Thelwall Thomas, in memory of members and associates of the Liverpool Medical Institution who gave their lives in the Great War.

WEST KENT MEDICO-CHIRURGICAL SOCIETY.—It is proposed to resume the annual dinner of the Society this year in June, but the dinner will not be held unless at least 20 members signify their intention to be present. Members who would like to attend are asked to communicate not later than May 27th with the hon. secretary, Dr. C. J. B. Buchan, 326, Brownhill-road, Catford, London, S.E. 6.

THE RETREAT (MENTAL HOSPITAL), YORK.—Dr. Bedford Pierce is resigning his position as medical superintendent of this hospital at the end of the year, after nearly 30 years' service. The committee of management have appointed as his successor Dr. Henry Yellowlees, at present the senior physician and deputy physician-superintendent of the Royal Edinburgh Asylum, Morningside.

FRIENDS' EMERGENCY AND WAR VICTIMS' RELIEF COMMITTEE.—The seventh report, just issued, covers the period from April 1st, 1920, to the end of March, 1921. In Austria, Poland, Germany, and Russia distress has been helped by the distribution of clothing and food, grants in kind to children's institutions, the importation of cows to increase the milk-supply for under-nourished children, by the feeding of students and the sale of clothing at reduced prices to impoverished middle-class people, and in other ways. In France the work has been closed down, but the Maison Maternelle de la Marne, the only institution in France devoted to the health and convalescence of mothers and babies, remains as a memento of the Committee's work. The total expenditure of the Committee for the year 1920–1921 was £700,000, the expenses for administration amounting to £18,500, or 2·67 per cent., a very modest figure. The address of the Relief Committee is 27, Chancery-lane, London, W.C. 2.

URBAN VITAL STATISTICS.

Irish Towns (Week ended April 30th).—The 141 deaths in Dublin corresponded to an annual rate of 17·4, or 1·0 per 1000 below that recorded in the previous week, and included 4 from infantile diarrhœa, and 1 each from measles and scarlet fever. The 133 deaths in Belfast were equal to a rate of 16·5 per 1000, and included 10 from whooping-cough.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Wednesday, May 18th.

SECTION OF HISTORY OF MEDICINE: at 5 P.M.
Annual General Meeting—Election of Officers and Council for 1921-1922.
Paper:
Dr. Charles G. Cumston (Geneva): A Brief Historical Summary of the Treatment of Trachoma, with Special Reference to the Arabian School and the Writings of Ali-Ibu-el-Aissa.

SECTION OF SURGERY: at 5.30 P.M.
Annual General Meeting—Election of Officers and Council for 1921-1922.
Exhibition:
There will be an exhibition of Specimens of Interesting Diseases and Tumours of Bone.

Thursday, May 19th.

SECTION OF DERMATOLOGY: at 5 P.M. (Cases at 4.30 P.M.)
Annual General Meeting—Election of Officers and Council for 1921-1922.
Cases: The following will be shown by—
Dr. Stowers: Effect of Brass Paste in the Treatment of a Case of Tuberculosis of the Skin.
Dr. H. W. Barber: (1) Epidermolysis Bullosa; (2) Multiple Rodent Ulcer; (3) Diphtheroid Infection of the Skin.

Friday, May 20th.

SECTION OF OTOLOGY: at 5 P.M.
Annual General Meeting—Election of Officers and Council for 1921-1922.
Demonstration:
Mr. J. S. Fraser: Demonstration on the Pathology of Deaf-Mutism.
Paper:
Mr. F. J. Cleminson: Sinusitis in Children.
Specimens:
Mr. Harry Brook: Exhibition of Casts of Congenital Malformations of the Ear and Artificial Ears.

SECTION OF ELECTRO-THERAPEUTICS: at 8.30 P.M.
Annual General Meeting—Election of Officers and Council for 1921-1922.

In consequence of the present industrial unrest the Council has decided not to hold the usual dinner this year. Instead of this there will be a clinical evening of an informal nature. The subject for discussion will be "The Stomach," opened by the President and Dr. Knox. There will also be a demonstration of the *Potter-Bucky Diaphragm.*

Any Member desirous of taking part in the discussion or who wishes to show skiagrams, &c., is requested to give notice to the honorary secretary, Dr. Stanley Melville, 9, Chandos-street, W. 1, at as early a date as possible.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, at 11, Chandos-street, Cavendish-square, W.
FRIDAY, May 20th.—7.45 P.M., Microscopic Demonstrations. 8.15 P.M., Papers:—Lieut.-Col. H. Kirkpatrick, I.M.S. (retd.): Some Points on Trachoma. Dr. C. H. Marshall: A New Method of Treatment of Human Trypanosomiasis. Mr. C. França: An Early Portuguese Contribution to Tropical Medicine.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.
TUESDAY, May 17th.—10 A.M., Dr. Robinson: Gynæcological Operations and Visit to Wards. 2 P.M., Mr. Banks Davis: Diseases of the Throat, Nose, and Ear. Dr. Morton: X Ray Department. Dr. Pernet: Skin Department. 5 P.M., Lecture:—*Dr. Burnford: Infective Endocarditis.*
WEDNESDAY.—11 A.M., Mr. MacDonald: Demonstration of Cystoscopy. 2 P.M., Mr. Gibb: Eye Department. Mr. D. Armour: Visit to Surgical Wards. 5 P.M., Lecture:—Dr. Owen: The Treatment of Nephritis. (II.)
THURSDAY.—10.30 A.M., Dr. Simson: Gynæcological Demonstration. 12 noon, Dr. S. Pinchin: Disease of the Heart. 2 P.M., Mr. B. Harman: Eye Department. Mr. Baldwin: Orthopædic Department. 5 P.M., Special Lecture:—Sir R. Armstrong-Jones: The Analysis of Mind and the Value of Psychotherapy (open to all medical practitioners).
FRIDAY.—10 A.M., Dr. G. Stewart: Neurological Demonstration. 12.15 P.M., Dr. Burnford: Applied Pathology. 2.30 P.M., Mr. Addison: Visit to Surgical Wards. Dr. Pritchard: Visit to Medical Wards. 5 P.M., Lecture:—Mr. MacDonald: Sexual Disabilities in the Male.
SATURDAY.—10 A.M., Dr. A. Saunders: Medical Diseases of Children. 2 P.M., Dr. Owen: Medical Out-patients. Mr. Sinclair: Surgical Out-patients.
Daily:—10 A.M. Ward Visits. 2 P.M., *In-patient, Out-patient* Clinics and Operations.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, W.C. 1.
MEDICAL SCHOOL.
TUESDAY, May 17th.—2 P.M., Out-patient Clinic: Dr. Grainger Stewart. 3.30 P.M., Dr. Risien Russell (Lecture Room): Demonstration of Cases.
THURSDAY, May 19th.—2 P.M., Out-patient Clinic: Dr. Farquhar Buzzard. 3.30 P.M., Lecture:—Mr. Scott: Investigation of Cases of Vertigo.
FRIDAY, May 20th.—2 P.M., Out-patient Clinic: Dr. Gordon Holmes. 3.30 P.M., Lecture:—Dr. Grainger Stewart: Spinal Caries.
Fee for Post-Graduate Course £7 7s. C. M. HINDS HOWELL, Dean.

LONDON HOSPITAL MEDICAL COLLEGE (UNIVERSITY OF LONDON), Turner-street, Mile End, E.
Courses of Lectures:—
A Course of Fourteen Lectures on Psycho-Neuroses, to be given by Dr. M. Culpin in the Clinical Theatre of the Hospital. Open *to Students of the Hospital and to* Members of the Profession.
TUESDAY, May 17th.—5.15 P.M., Lecture V.:—Conflict and Repression.
FRIDAY.—5.15 P.M., Lecture VI.:—Symbolism; Displacement of Affect.
Advanced Lectures in Physiology, to Students of the University and to others interested in the subject.
A *Course of Eight Lectures on Reception of Sensory Stimuli*, to be given by Prof. H. E. Roaf in the Physiology Theatre.
THURSDAY.—4.30 P.M., Lecture II.

ST. BARTHOLOMEW'S HOSPITAL (UNIVERSITY OF LONDON), West Smithfield, E.C.
A Course of Eight Advanced Lectures in Physiology, to be given in the Physiological Laboratory, to Students of the University and others interested in the subject.
TUESDAY, May 17th.—4.30 P.M., Lecture III.:—Dr. J. Barcroft: Alpinism.

LONDON (ROYAL FREE HOSPITAL) SCHOOL OF MEDICINE FOR WOMEN (UNIVERSITY OF LONDON), Hunter-street, W.C.
Post-Graduate Course of Instruction in Treatment of Venereal Diseases.
A Course arranged by the London (Royal Free *Hospital*) School of Medicine for Women, the Royal Free Hospital, the Elizabeth Garrett Anderson Hospital and the London Lock Hospital, for the instruction of qualified medical women in the Treatment *of Venereal Diseases. The Course* will extend over two weeks.
TUESDAY, May 17th.—10 A.M., Introductory Lecture—Mr. J. E. R. McDonagh: Some Aspects of the Venereal Problem (at 8, Hunter-street, W.C.) 2 P.M., Mr. C. Gibbs: Clinical Demonstration and Visit to Wards (at the Female Lock Hospital, Harrow-road). 6.30 P.M., Dr. Ruth Balmer: Out-patient Cliniques for Women and Children (at the Elizabeth Garrett Anderson Hospital, 144, Euston-road, N.W.)
WEDNESDAY.—11 A.M., Dr. D. Thomson: Pathological Lecture and Demonstration (at the London Lock Hospital, 91, Dean-street, W.) 3.30 P.M., Mr. J. E. Lane: Clinical Demonstration by *and Visit to Wards and Out-patient Department* (at the London Lock Hospital, Harrow-road).
THURSDAY.—2 P.M., Mr. J. E. R. McDonagh: Clinical Demonstration by and Visit to Wards (at the London Lock Hospital, *Harrow*-road). 5 P.M., Mrs. Rorke, M.B.: Injections (at the Royal Free Hospital, Gray's Inn-road).
FRIDAY.—10 A.M., Mrs. Rorke, M.B.: Treatment Ante-natal Cases (at the Royal Free Hospital). 5 P.M., Mr. J. J. Abraham: Clinical Demonstration, Injections, and Out-patient Clinique for Women and Children (at the London Lock Hospital, 91, Dean-street, W.). 6.30 P.M., Dr. Ruth Balmer: Out-patient Cliniques for Women and *Children* (at the Elizabeth Garrett Anderson Hospital).

TAVISTOCK CLINIC FOR FUNCTIONAL NERVE CASES, 51, Tavistock-square, W.C.
A Course of Ten Lectures on Elementary Psychotherapy, to be given by Dr. H. C. Miller, at the Kingsway Hall, Kingsway, W.C.
FRIDAY, May 20th.—5.15 P.M., Lecture III.: Conscious Mental Methods; Persuasion; Suggestion; Hypnosis; Faith-healing; Quackery.

INSTITUTE OF PATHOLOGY AND RESEARCH, St. Mary's Hospital, in the Lecture-room of the Bacteriological Department.
A *Course of Lectures on Pathological* Research in its Relation *to* Medicine, open to all Members of the Profession and Students.
THURSDAY, May 19th.—4.30 P.M., Dr. H. H. Dale: Anaphylaxis and Immunity.

CHADWICK PUBLIC LECTURE, in the Lecture Room, Medical Society of London, 11, Chandos-street, Cavendish-square, W.
THURSDAY, May 19th.—5.15 P.M., Dr. W. Hunter: Fevers in England—their Prevention and Control, with Special Reference to the Effects of Public Health Acts (1848-1918). Lecture III., Period 1891-1920—Compulsory Notification and Isolation.

ROYAL INSTITUTION *OF* GREAT BRITAIN, Albemarle-street, Piccadilly, W.
FRIDAY, May 20th.—9 P.M., Discourse:—Prof. E. H. Starling: The Law of the Heart.

MANCHESTER FRENCH HOSPITAL POST-GRADUATE LECTURES, 24, Acomb-street, Whitworth Park.
Special Course of Lectures in Gynæcology.
WEDNESDAY, May 18th.—11 A.M., *Demonstration Operations.*
THURSDAY.—4.30 P.M., Lecture VI.:—Dr. A. C. Magian: Parasites of the Genital Tract.

Notes, Short Comments, and Answers to Correspondents.

OUTLINE OF A SCHEME TO FINANCE THE VOLUNTARY HOSPITALS OF LONDON.

BY W. MCADAM ECCLES, M.S., M.B., F.R.C.S.

THE committee appointed by Dr. Addison to look into and report on the finances of the voluntary hospitals strongly urged[1] the retention of the voluntary system of finance and management. King Edward's Hospital Fund for London has come to the same conclusion,[2] and with this two-fold decision most of the lay authorities and medical staffs of the hospitals concerned agree. The problem, therefore, is how to maintain voluntary contributions so that voluntary management may remain.

In 1920, 113 London general and special voluntary hospitals spent nearly £3,000,000, while their income fell short of this by some £500,000. With this deficit unchecked the road to bankruptcy is sure. Since 1911 these voluntary hospitals have been treating without payment as in-patients persons insured under the National Health Insurance Acts. Meanwhile the approved societies have been accumulating funds, possibly amounting to £7,000,000. Lord Cave's Committee suggested that some of this accumulation should be disbursed in grants to the voluntary hospitals, but it is doubtful whether the approved societies could or would part with the money in this manner. The societies are, however, desirous of providing extra "benefits" for their members.

Wider Application of the Sussex Scheme.

In January of this year a scheme devised by Dr. Gordon Dill of Brighton was started in Sussex and is proving remarkably successful. Its application to London, and possibly to the whole of England, is now under consideration. In brief, it is as follows: All those whose incomes do not exceed £250 a year can become members by subscribing £1 per annum (equivalent to 4·6*d.* per week); a married couple without children, whose combined income does not exceed £400 a year, can both be members for the subscription of £1 10*s.* for the two; and married persons with children under 16 years of age, whose combined income does not exceed £500, can themselves and their children all become members for an inclusive subscription of £2. For this yearly voluntary subscription the following facilities are to be arranged:—

1. Consultations in the patients' own homes, when too ill to leave them. Consultations separate from other patients at the coöperating hospitals.
2. A motor ambulance service.
3. In-patient hospital maintenance and treatment.
4. Dental treatment.
5. Laboratory investigations, X ray, electrical, and massage treatment.
6. Nurses' services in the homes.

Access to all the facilities will be available only on the application of the patient's own general practitioner, and with the approval of the members of the hospital staff concerned.

Budget as Applied to London.

It is estimated that in the area of the Metropolitan and City Police districts there are some 5,000,000 persons, men, women, and children to whom the scheme applies. If all these joined as individuals, married persons, or families, the resulting income would be about £3,000,000 per annum. If as a basis for calculation it is assumed that sufficient persons join to produce an income of £1,200,000 this might be allotted as follows:—

	£		£
Hospitals, 52/80 (including 25 per cent. to medical staff fund, £195,000) ...	780,000	Visiting consultants, 8/80	120,000
500 nurses, 6/80	90,000	Administration, 3/80 ...	45,000
30 ambulances, 2/80	30,000	Reserve, 9/80	135,000
			£1,200,000

From these figures it will be seen that—

(1) The hospitals would receive £585,000 net, or £85,000 over and above their deficit in 1920.

(2) The medical staff fund would amount to £195,000, which would be administered in any way the staffs attached to the hospitals determined. From part of this comparatively large fund a really well-organised post-graduate medical school in London might be financed.

(3) 500 nurses at £180 each per annum could be provided.

(4) 30 motor ambulances, each provided with two skilled men and costing £1000 per annum, could be at the service of the general practitioner and the hospitals.

(5) 38,000 consultations in the patients' own homes at £3 3*s.* could be provided for.

(6) The cost of administration and reserve contingencies are well covered.

The Advantages of the Scheme.

Great advantages lie in the scheme, some of which may be mentioned—namely, (*a*) to the *prospective patient*: (1) Provision made during health; (2) free consultations at home; (3) no payment for hospital maintenance or treatment during illness; (4) freedom for almoner's investigation; (5) dental treatment; (6) ambulance service; (7) the feeling of satisfaction that his subscription is of help to others less fortunate.

(*b*) To the *hospital*: (1) Maintenance of the voluntary system, both of income and management; (2) an adequate income; (2) freedom from necessity of making appeals.

(*c*) To the *general practitioner*: (1) All the arranged facilities will be obtainable only through the general practitioner; (2) much saving of anxiety by being able to arrange a consultation free of charge; (3) can maintain more direct contact with his patient; (4) can obtain promptly many facilities hitherto difficult or costly to procure.

(*d*) To the *consultant members* of the medical staff of the voluntary hospitals: (1) A medical staff fund of 25 per cent. of the money received by the hospital; (2) a fund from which consultants will be paid for consultations at patients' own homes; (3) more direct relationship with general practitioners.

(*e*) To the *nation*: (1) The maintenance of the voluntary system; (2) the prompter treatment of cases of serious illness needing in-patient hospital treatment, with corresponding saving of life and shortening of convalescence; (3) the maintenance of a supply of clinical material for medical and nursing education in the schools.

Some Objections to be Met.

Some cogent objections have been levelled at the scheme. The *first* is that it would not be successful because there is not enough inducement to make a sufficient number join to produce at least £1,200,000 a year. This may be answered by stating that the facilities offered are greater than those at present obtainable, and all these facilities will be obtained free at the time required. Further, the voluntary hospitals may have to say in the future that they can only treat without payment the really necessitous poor and members of the scheme.

Secondly, it may be thought that if the scheme is successful it would greatly diminish the number of the ordinary voluntary and other subscriptions. This would probably be true, but the gain in income would completely counterbalance this loss, and the more so the greater the success of the scheme. If £3,000,000 came in from subscribers to the scheme this would cover the whole of the yearly cost of the hospitals in London. Again, it is stated that if the scheme is successful it would necessitate additional beds, but if successful to this extent there would be money enough to provide the extra accommodation.

And, *lastly*, it is argued that the cost of running the scheme would be great. This is true, but not a penny of it would fall upon the hospitals, and the greater the success of the scheme the less proportionately would be the cost of administration.

No scheme put forward appears to have all the merits of this particular one conceived by Dr. Gordon Dill. If a success, it would be a tremendous boon; *if a failure*, it can hardly leave the voluntary hospitals worse off than they are. The approval and coöperation of the lay authorities of the hospitals, the medical staffs, the general practitioners, the approved societies, and the persons who may need the facilities should ensure the abundant success of the scheme.

---

[1] Interim Report, March 8th, 1921.

[2] Interim Report of the King's Fund Policy Committee, April 12th, 1921.

PUBLIC HEALTH OF SEYCHELLES.

IN his report for 1919 the Governor, Sir Eustace Fiennes, states that the population of the colony is now estimated at 24,653. The birth-rate for the year was 25·19 and the death-rate 16·84 per 1000. There was an epidemic of influenza which affected the majority of the population and caused 115 deaths. There was also an epidemic of dengue fever. It was noticed that the number of cases of lobar pneumonia had considerably increased. During the year the lepers were brought from Round Island, Praslin, 35 miles away, to Round Island, Mahe, where they are now comfortably housed in good quarters and are well cared for, the doctor making regular visits to the island. The in-patients treated at Victoria Hospital in 1919 numbered 723, and 4739 persons were treated at the dispensaries. The rainfall was considerably higher than in 1918, being 101·03 inches; rain fell on 135 days.

THE STABILITY AND INFLUENCE OF THE ANTI-SCORBUTIC VITAMIN.

THE vulnerability of the anti-scorbutic vitamin has been the subject of many researches, and recently this question has attracted considerable attention in the United States. In 1918 M. H. Givens and H. B. McGlugage showed that the raw tomato is an efficient antiscorbutic agent, that this fruit can be subjected to a temperature of 55°-60° C. for 14-24 hours, or 35-40° C. for 36-44 hours and still retain a considerable content of its antiscorbutic vitamin, and that this treated material is still potent after three months ageing. A. F. Hess at the same time proved that canned tomatoes are effective as antiscorbutic agents for children and guinea-pigs even if canned for a year, so that their antiscorbutic value does not diminish appreciably by ageing. Feeding experiments on guinea-pigs determined the effect of heat and age upon the antiscorbutic accessory. It was found that guinea-pigs are protected against scurvy by daily doses of 2·5 g. of fresh raw tomatoes; by 10 g. of fresh raw tomatoes heated one hour at 100° C.; by 2 g. of dried tomatoes heated 15 minutes at 100° C.; by 10 g. of tomatoes canned at 15 pounds pressure for 30 minutes; by 3 c.cm. of commercial canned tomatoes three years old; and by 10 g. of commercial canned tomatoes, three years old, cooked 15 minutes at 100° C. The same observers, with E. G. van Horne, investigated at the University of Rochester the antiscorbutic property of raw, dried, and cooked apples and bananas, the two fruits most generally consumed in the United States by healthy adults, children, and, indeed, by the sick. An attempt to determine quantitatively their antiscorbutic potency in the raw and in the cooked form was made by feeding guinea-pigs on a basal diet adequate in all respects except the antiscorbutic vitamin, with the result that a dose of 10 g. per diem of raw apples or of bananas was found to protect a guinea-pig against scurvy for three months. On the other hand, an equivalent amount of these foods cooked at 100° C. for 15 minutes or dried at 55°-60° C. (with the exception of dried apples, which showed some antiscorbutic potency) or dried at 55°-60° C. and cooked for 15 minutes at 100° C., will not protect the animals against scurvy. The researches of A. F. Hess and L. J. Unger on the destruction of the antiscorbutic vitamins by oxidation were recalled in THE LANCET of last week.

The pathogenesis of deficiency disease opens up a very wide subject, and the relation of the scorbutic condition to certain of the endocrine glands has been the subject of various investigations. We have already referred[1] to certain observations of V. La Mer and H. L. Campbell on changes in organ weight produced by diets deficient in antiscorbutic vitamin, more especially a pronounced increase in weight of the adrenal glands. These observers do not appear to have paid special attention to the histo-pathological changes occurring in guinea-pigs fed on a scorbutic dietary, but they confirm the earlier observations of R. McCarrison, who has published several papers on the pathogenesis of deficiency disease, not the least interesting of which is No. IV., on the Influence of a Scorbutic Diet on the Adrenal Glands, illustrated with several plates.[2] McCarrison showed that a scorbutic diet gives rise in guinea-pigs to (1) an increase in size and weight of these glands; (2) a marked diminution in their adrenalin content, causing pronounced depreciation in their functional capacity; (3) hæmorrhagic infiltration around the periphery of the adrenal cortex; (4) degenerative changes in the cellular elements of the cortex and medulla. The impairment of adrenal function occurs before clinical evidence of scurvy becomes manifest. It is clear that we are still far from a full knowledge of the far-reaching effects of any one single vitamin in metabolic activity, and much spade-work will have to be done before the relation of vitamins to endocrine glands are laid bare.

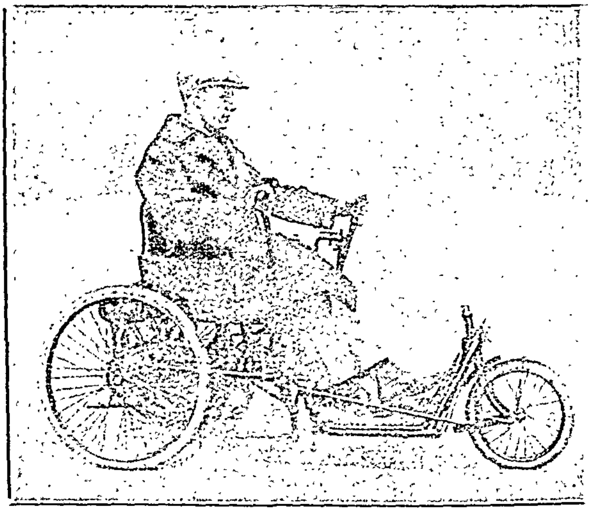
CAMBRIDGE MICROTOMES AND RECORDING THERMOMETERS.

List No. 182 of the Cambridge and Paul Instrument Company, Ltd. (45, Grosvenor-place, London, S.W. 1), describes three types of Cambridge microtomes manufactured to meet the requirements of many different classes of work. A new universal microtome offers the advantages of ease of manipulation, rigidity, and continued accuracy, even after considerable wear, which are characteristic of the "rocker," with the additional advantage that it cuts flat sections. It is capable of cutting sections from objects embedded in paraffin or celloidin, or from certain non-embedded objects. Ribbons of sections can be obtained from paraffin-embedded objects. The rocking microtome differs only in minor details from the patterns of previous years. It remains a favourite instrument for cutting sections of paraffin-embedded objects, and with it long ribbons of uniform sections can be produced with ease and rapidity. The freezing microtome is designed for cutting sections of tissues during the progress of surgical operations.

List No. 183 describes instruments designed for the continuous registration of body temperatures, developed as a result of the work of Sir G. Sims Woodhead and Mr. P. C. Varrier-Jones, recorded in our columns ("Investigations on Clinical Thermometry," THE LANCET, 1916, i., 173, 281, 338, 450, and 495). The instruments have proved reliable and easy to manipulate, and of ample sensitivity for the requirements of ordinary practice. The thermometers are of the electrical resistance type, and consist essentially of a bulb containing a coil of platinum wire joined by connecting wires to a recorder which may, if desired, be placed at a considerable distance from the patient.

MOTOR-ESEGO TRICYCLE.

THE machine here illustrated is primarily a standard model hand-propelled tricycle, but fitted with a petrol motor auxiliary unit, giving a speed of 2-15 miles per hour, and an invalid is able to climb hills of any gradient. The engine is easily started by two or three motions of the hand levers, the hand clutch is then released, the propelling levers remain stationary, and the machine is under perfect control. One important feature of this machine is that in the event of the motor not functioning for any reason the rider is able to propel the machine home by means of the hand levers.



The Motor-Esego tricycle in use.

The machine is manufactured by Carters Ltd., of 125-9, Great Portland-street, London, W. 1.

THE HOMELESS CHILD FOR THE CHILDLESS HOME.

MEDICAL men are occasionally asked by those wishing to adopt children if they know of a suitable orphan or homeless child, and more frequently about the chances of finding foster-parents for an infant whose mother cannot make a home for it. The responsibility of direct introduction of principals is often shirked, while a recommendation to either side of a reputable society who will make the necessary inquiries is an easy and safe procedure. The National Adoption Society (registered as a benevolent society under the Friendly Societies Act) was founded before the war by Rev. W. F. Buttle. The committee includes Lady Dawson of Penn, Dr. Charles Porter, and Lady Ryall, and the honorary medical administrator is Dr. Margaret Rorke. Applications are constantly being received from both parties; those from adopters who require payment or premium are refused. Every home to which a child is sent is visited by a member of the Society. The following general summary for one year gives an idea of the numbers dealt with:—

Applications for adoption	1975
Applications for babies	734
Adoptions completed	204

Further information and application forms are obtainable from the Secretary, National Adoption Society, 2 Baker-street, London, W. 1.

The Goulstonian Lectures

ON

GLYCÆMIA AND GLYCOSURIA.

Delivered before the Royal College of Physicians of London

BY GEORGE GRAHAM, M.A., M.D. CANTAB., F.R.C.P. LOND.,

SECOND ASSISTANT, MEDICAL CLINIC, ST. BARTHOLOMEW'S HOSPITAL; ASSISTANT PHYSICIAN, GREAT NORTHERN CENTRAL HOSPITAL.

LECTURE III.*

(Delivered on March 8th, 1921.)

IN my first two lectures I have spoken about the fate of the sugar in the blood and the types of diabetes mellitus which are already recognised. In this lecture I shall briefly discuss the hypotheses for the cause of diabetes, and then go on to discuss the principles and details of the modern treatment.

CAUSATION AND TREATMENT OF DIABETES.

The association of the pancreas with the disturbance of sugar metabolism has been completely established by the work on the extirpation of the pancreas. The original observations of Minnowski and von Mering have been greatly extended by Allen's work. Further, the islands of Langerhans are recognised as distinct entities, mainly as the result of the work of Bensley[1] and Homans,[2] and the pancreas is therefore a double gland with its external secretion into the intestine and internal secretion into the portal vein. It is also believed that the islands are concerned with the metabolism of sugar, as definite changes occur when the surviving remnant of the pancreas of a dog is overworked. It would seem therefore that the association is one which could easily be confirmed by post-mortem examination. The state of the islands in dogs in whom diabetes has been produced by removal of a large fragment of the pancreas coupled with excessive carbohydrate feeding does suggest it. These cases show hydrops of the cell, and the characteristic granules are absent; the cells have an exhausted appearance. In long-standing cases, however, it is difficult to make out changes, as the cells gradually die and there may be no sign of hydropic degeneration (Allen[3]). In man the evidence is by no means so good. This is partly due to the long-standing nature of the disease and partly to the fact that the pancreas undergoes very rapid changes after death. By its position in the body it is kept very warm, and is usually invaded early by bacteria. Unfortunately, it cannot often be examined soon after death. Further, the staining reactions of the ordinary acini are usually very poor in comparison with those obtained from a fresh specimen. Consequently it is not really surprising that the finer details, such as the presence or absence of granules in the cells of the islands, cannot readily be made out.

Opie[4] observed that the fibrosis which is seen in the pancreas may involve the islands of Langerhans, but these may escape if the changes are chiefly around the acini. Weichselbaum and Stangl[5] have greatly extended Opie's work; they pointed out that there was also a change in the cells of the islands, which they called hydrops of the cells. The discovery of the specific granules by Bensley has added a further test of the functional activity of the cells. If the pancreas of diabetic patients is examined fairly early it is possible to form some idea whether the islands are affected or not. One of the difficulties is that changes of this kind do occur in the island cells of patients who have never had diabetes. It is therefore necessary to examine many portions of the pancreas so as to form some idea of how many of the islands are affected. Allen[6] has recently stated that working under these conditions he has been able to make a correct diagnosis in nearly 100 per cent. of the cases of diabetes and non-diabetics that he examined. If the pancreas was badly preserved it was not possible to give an opinion.

This work establishes the hypothesis that the islands of Langerhans are intimately related to diabetes, but the cause of the damage to the islands remains obscure.

Hypothetical Causation of Glycosuria.

Extensive involvement with a neoplasm very rarely causes glycosuria. General diseases of the pancreas, such as acute and chronic pancreatitis, rarely cause more than a transient glycosuria. This is probably due to the fact that the islands are little affected by the disease which has affected the acini. Thirloix[7] has completely destroyed the acini of the pancreas of a dog by injecting into the duct a mixture of oil and lampblack without causing any glycosuria. Also the amount of pancreas which is necessary in the dog to prevent glycosuria is small; the survival of a one-eighth to one-ninth of the gland is sufficient (Allen[8]).

Syphilis of the pancreas may be a factor in causing glycosuria in some cases.

Warthin[9] found definite changes in the pancreas which he regarded as characteristic of syphilis in 13 out of 14 cases of diabetes. In 2 cases the *Spirochæta pallida* was found in the pancreas and in 5 cases in the myocardium. Fibrosis of the islands was well marked in 11 out of 13 cases. Warthin did not assert that syphilis was the cause of diabetes, but only that it was a common cause of interstitial pancreatitis, and that if interstitial pancreatitis is the cause of diabetes syphilis must play a large part in its causation. Whether or no syphilis is the prime cause of the diabetes it may well be a contributing factor in causing a gradual destruction of the islands, and so of the gradual decrease of sugar tolerance with which the clinician is so familiar.

Since the general diseases to which the pancreas is liable do not seem to produce marked changes in the sugar tolerance it is permissible to speculate whether the islands can be affected by a specific agent which affects them without damaging the rest of the pancreas.

The evidence in favour of this hypothesis is slight at present. The instances of sudden onset of very severe diabetes which I mentioned in my last lecture suggest that a very widespread damage may be done to the islands throughout the pancreas. It is difficult to conceive on our present knowledge how this damage can be done. There is no evidence of any infecting organism, and only one of my cases had any other symptoms besides thirst. In this case malaise was complained of and the boy was kept in bed for three days, and then returned to school for three days before being admitted to hospital. We do not know any real parallel to such an infection. It is true that the pancreas is damaged in acute pancreatitis—a disease of which we do not know the cause. Mumps affect the salivary glands, but may also affect the pancreas (Feiling[10]) and the testicles.

The evidence for a specific toxin or chemical poison is very little stronger.

It is true that the tetanus toxin is specific for the motor neurons and for no other part of the nervous system. But even if there is a specific toxin for the islands, there is no evidence where or how it arises. The evidence, therefore, for any specific agent which could damage the islands is very slight.

If, however, the islands are affected by such a specific agent it is much easier to explain the different grades of severity of diabetes which occur. In the mild cases comparatively few islands would be damaged, but in severe cases the number of islands destroyed would be very great. The gradual decrease of tolerance can be explained as being due to the destruction of more islands.

It has been suggested that stimulation of the sympathetic nervous system may play a considerable part in the causation of diabetes, and this view has recently been put forward by Langdon Brown in the Croonian lectures, 1918.[11]

It is accepted, as I pointed out in my first lecture, that stimulation of the splanchnic nerves produces glycosuria by causing an increased output of adrenalin. This may well play a part in the causation of the mild type of diabetes which occurs in elderly people with many business worries. It can also increase the amount of sugar excreted in other cases, but it does not seem probable that it can be a cause of severe diabetes. Allen's[12] criticism that stimulation of the sympathetic system can only produce glycosuria if the pancreas is already damaged does not agree with the observations of McLeod[13] on the healthy football players who passed sugar while watching a football match. But it is obvious that if the pancreas is damaged sugar will be more readily excreted after splanchnic stimulation.

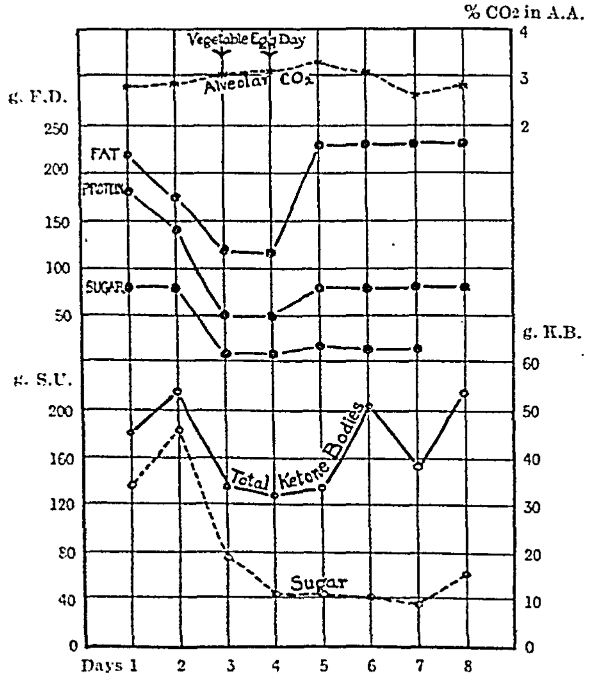
No. 5099.

Treatment with Extracts of Pancreas.

Since we are still in ignorance of the cause of diabetes there is no chance yet of any preventive treatment. As the disease is probably due to the damage of the islands of Langerhans, I must first of all consider the question of treatment with extracts of pancreas. Many attempts have been made to treat cases with extracts of the gland on the line of the successful treatment of myxœdema with thyroid extract. These, however, have all been failures, and no improvement has resulted.[14] The attempt to graft a portion of a healthy pancreas into a patient is likely to fail for the following reasons:—

> In order to make a successful transplant of a gland it is essential that the graft be taken from a member of the same species. Fresh human pancreas is exceedingly difficult to obtain, but I have been told of one unpublished case (Grant) where the graft was made from the pancreas of a man who had just died of a head injury. It is possible to obtain a pancreas in this way a few minutes after death. It is also essential that the donor should belong to the same blood group as the patient.
>
> Further, the gland must be placed in a position in which the internal secretion can pass to the liver via the portal vein, as Hedon[15] showed that it was only efficacious under these conditions. This fact adds considerably to the difficulty, and it would be necessary to open the abdomen in order to place the graft in the portal circulation, and diabetics stand an operation badly in any case. Pratt[16] has succeeded in one case in making a graft in a dog by burying the gland in the spleen. Most cases of transplantation cannot be said to be successful.

The attempt to influence the sugar metabolism directly by means of drugs has now been given up as useless.



g. F.D. = grammes food in diet. g. S.U. = grammes sugar in urine.
A.A. = alveolar air.
g. K.B. = grammes ketone bodies in urine.

FIG. 1.—Showing effect of a vegetable and egg day on output of sugar, total ketone bodies, and alveolar CO2.

Codein, which had a great vogue at one time, is of little value except in the later stages of the disease, when it makes the patient's life more tolerable by its sedative action. By soothing the patient's temper sympathetic stimulation may perhaps be diminished and the glycosuria may decrease. Two kinds of drugs are, however, of use for other reasons: (1) One of the complications of diabetes is the severe constipation which almost always occurs. This can be treated with a mechanical adjuvant such as liquid paraffin, or better still by agar-agar. The drugs which are of most use are the saline purgatives to which tr. jalapæ in ʒss. or ʒi. doses may be added. Large doses of aloes are of great assistance. The successful treatment of the constipation will be of great benefit to the patient. (2) It is important to maintain the general health of the patient as far as possible, and tonics like strychnine which do not contain any sugar are of some assistance.

As there are no specifics for the treatment of diabetes we are reduced to attempting to correct chemical errors which result from the absence of the internal secretion.

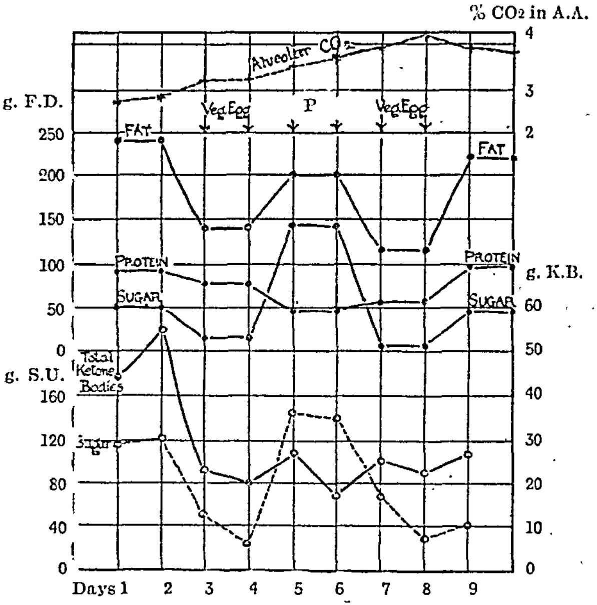


FIG. 2.—Showing effect of a vegetable and egg day followed by potato days on output of sugar, total ketone bodies, and alveolar CO2. P = potato day.

Tests on Animals.

An exhaustive survey of the modes of treatment has recently been given by Allen, Stillman, and Fitz, of the Rockefeller Institute, and I need only refer in passing to work of different men.

The admirable work of the German schools of Naunyn and von Noorden did not really advance treatment very much, although it paved the way for it. The brilliant but ill-balanced work of Guelpa was largely overlooked because of the exaggerated claim which he made for the treatment of other diseases by starvation and purgation, and also because he neglected the after-treatment. The work of Allen and his school on animals has very greatly advanced the treatment.

The advantages of testing different kinds of treatment on animals, which cannot resist to anything like the same extent as patients, are very great. The difficulty which Allen surmounted was that although diabetes does occur naturally in dogs it is very rare. Further, the diabetes which was produced by complete removal of the pancreas was so fatal that no treatment was of any avail in prolonging life more than a few days. Partial removal of the pancreas, on the other hand, did not produce diabetes. Allen, however, overcame this difficulty by removing more and more of the gland in successive operations until the animal became a diabetic of the grade which he required. He found that he could cause a mild diabetes if the remnant of the gland was one-eighth to one-ninth of the whole gland.[8] The diabetes was severe if the remnant was less than one-ninth of the whole gland. These results were liable to variation, as the presence of a local inflammation rendered the diabetes more severe. On the other hand, some hypertrophy of the gland sometimes occurred. The dogs with the varying grades of diabetes were then treated in different ways and the results observed.

Tests on Human Beings.

The treatment, which was of value, was then tested on patients under the charge of Stillman at the Rockefeller Institute and of Joslin at Boston.

The general principle on which Allen's diet[17] is based is that of under-nutrition of the patient. Starvation is enforced until the patient ceases to pass sugar in the urine. Carbohydrates are then added to the diet in the form of vegetables, and the amount is increased until sugar is excreted. Then the carbohydrate is decreased, and amounts of protein are added until 1·5 g. of protein per kilo is given. Thirdly, fat is added until the caloric value of the diet is sufficient. The essential point is that sugar should never be excreted in the urine, and further, that the fasting value of the blood sugar should be within normal limits. It is important to note that Allen makes no exaggerated claim for his treatment, as he makes it quite clear that a cure in the true sense of the word cannot be expected.

Conversion of Mild into Severe Type.

More recently Allen[18] has been studying the different methods by which a mild diabetic animal may be converted into a severe diabetic.

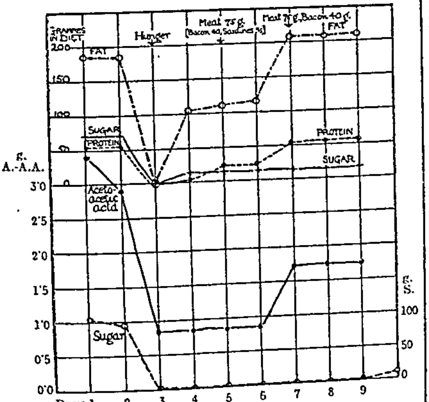
He found that overfeeding with sugar was the best way of converting the mild case into a severe one. The continual overfeeding led to a steady decrease in the sugar tolerance, and the islands of Langerhans showed absence of granules and hydrops of the cell. Similarly, overfeeding with starch converted the mild case into a severe one. Overfeeding with proteins also produced the same effect, but more slowly than in the case of sugar or starch. I will consider the significance of these experiments later on.

As so often happens, other workers had independently and for very different reasons arrived at a somewhat similar plan of treatment. In 1915 Williamson[19] had advocated the use of small quantities of casein and cream, but he did not apply it to very severe cases.

Personal Experiments.

I will now describe some of the experiments which led me independently in 1915 to arrive at a line of treatment which, although it differs from the Allen diet in its details, is based on the same general principle of under-nutrition. The work was interrupted in 1915, and although it has been referred to[20 21 22] it has never been published. My interest in diabetes really dates from 1913, when Hurtley gave a communication to the Biochemical Society on the problems of ketosis.

Hurtley had been working at these problems with the coöperation of Sir Archibald Garrod since 1907, and his work on the four carbon atom acids of diabetic urine is a most valuable contribution to our knowledge of the problems of ketosis.[23] Hurtley realised quite early that it was essential to estimate the acetone bodies in the urine when the carbohydrate of the diet was being reduced. If the carbohydrate was reduced below a certain amount there was a sudden rise in the excretion of the acetone bodies which was very difficult to control by the giving of more carbohydrate. The acetone bodies could be reduced, however, if the patient was given the diet of vegetables and eggs, which was part of the régime of von Noorden's oatmeal cure. This sudden decrease in the acetone bodies interested us greatly, and it was to try to elucidate this point that I first joined Hurtley in making the estimations of the alveolar CO_2 and of the ammonia output, in addition to the other estimations. The second patient we examined had a very severe form of diabetes, and had at one time been treated by a prolonged fast after the Guelpa idea. (Fig. 1.)



g. A.-A.A. = grammes aceto-acetic acid. g. S. = grammes sugar.

FIG. 3.—Showing effect of a hunger-day, followed by a gradual increase of diet, on output of sugar and aceto-acetic acid.

The sugar output was high, as 189 g. were excreted, although only 80 g. of sugar were eaten. The total acetone bodies were very high, as 54 g. were excreted. When the vegetable and egg diet was given there was a decrease in the sugar output to 47 g. on the second day; of the acetone bodies to 32 g. The alveolar CO_2 rose from the very low figure of 2·8 per cent. to 3·3 per cent., but then declined again. In this experiment the fat in the diet was decreased from 220 g. to 117 g., the protein from 180 g. to 50 g., and the sugar from 80 g. to 12 g. As both the fat and the protein were decreased the reduction in the acetone bodies might have been due to the reduction of either the fat or the protein or both. (Fig. 2.) In the next experiment on the same patient the fat was diminished from 240 g. to 140 g., while the protein was only decreased from 94 g. to 78 g., and the sugar from 50 g. to 10 g. In this case the total acetone bodies decreased from 55 g. to 20·5 g.—that is, the decrease was rather more than in the previous experiment. This experiment strongly suggested what is now well recognised, that the acetone bodies are almost entirely formed from fat. On the next two days 135 g. of potatoes were given and 200 g. of butter. The output of total acetone bodies at first rose to 27 g., but then fell to 17 g. The sugar output was slightly more than the intake—i.e., 142 g. The alveolar CO_2, which was very low at 2·8 per cent., rose steadily through the experiment and reached its maximum at 4·2 per cent. on the fourth vegetable and egg day, but then began to fall.

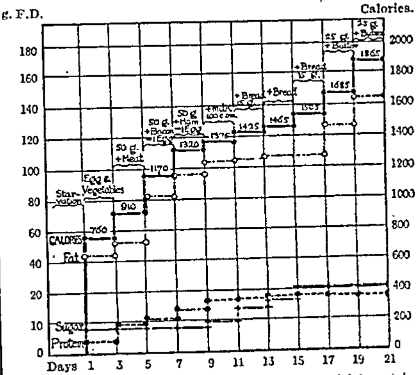


FIG. 4.—Showing total caloric values, and grammes of fat, protein, and sugar, in the "ladder diet."

This is the typical result in a very severe case of the complete régime of von Noorden with the two vegetable and egg days, two potato days, and two more vegetable and egg days. This régime always produced a great temporary improvement, but on the return to the original diet there was an immediate increase in the sugar and acetone bodies in severe cases. We treated several other cases in a similar way and not until April, 1915, was any real advance made. This patient had a severe type of diabetes, but much less severe than the previous patient. Gradual reduction of the carbohydrate in the orthodox manner had failed to reduce the sugar output below 100 g. of sugar on an intake of 70 g. The aceto-acetic acid output was 3·4 g. and in this experiment, as I was working alone, no estimations of the β-oxybutyric acid were made. On two occasions two vegetable and egg days had been tried with temporary benefit only.

On this occasion I decided to try the effect of a complete starvation day (Fig. 6, Lecture II.), but I did not give the abundant purgatives which Guelpa recommended. (Fig. 3.) 1 g. of sugar was excreted and only 0·84 g. of aceto-acetic acid. On the next day vegetable and eggs were eaten, and as he was not passing any sugar and as the aceto-acetic acid output was so low, 0·84 g., I decided that I would not return to the original diet, but increase the food gradually. Therefore, 75 g. of meat were added to the diet on one day. On the next day 40 g. of bacon and 35 g. of sardines were added. One day later the meat was increased to 150 g. and the bacon to 80 g. During this period no sugar was excreted and the aceto-acetic acid output was 1·7 g. At this point some diabetic bread was added and sugar was excreted.

This was the first time that I had tried to increase the diet slowly, although I now regard the increase as a very rapid one. The starvation and gradual increase of the diet was repeated, and the man went out of hospital passing no sugar.

This plan of diet with considerable modifications was tried on eight other patients in 1915 with considerable success, as four of them were on the verge of coma on admission to the hospital. At this stage the work had to be left unfinished, and could not be resumed again until early in 1919, although Dr. Langdon Brown continued to use the ladder diet with success on his patients.

Routine Now Followed.

The diet which we now use remains the same in its general plan, but has been modified in various ways as the result of reading Allen's work and further experience of treating patients. The general routine which we now use is as follows (Fig. 4):—

The patient is allowed his ordinary diet on the first day on which he enters hospital with the addition of 600 c.cm. milk and 50 g. bread unless he is on the verge of coma. The amount of sugar which is passed in this portion of the day is estimated and gives a rough idea of the severity of the disease. Two days' starvation are then given, tea, coffee, meat extract, and as much water as is desired being allowed. Whether the urine is sugar-free or not, the patient is not allowed to fast more than two days at a time. On the third and fourth days the egg and vegetable diet of 5 eggs, 50 g. butter, and 300 g. greens is given. If the patient is still passing sugar two more fast days are given, and this is alternated, as a rule, until the urine is sugar-free or the attempt to get it sugar-free has to be abandoned. If the patient is sugar-free 50 g. of meat are added to the midday meal for two days. On the seventh and eighth days 50 g. of ham are added for tea and one egg is taken away. On the ninth and tenth days 50 g. of bacon are given at breakfast and one egg is taken away. If the patient passes traces of sugar on two successive days he is put back to the bottom of the ladder and made to climb up again. If no sugar is passed 100 c.cm. of milk are given on the eleventh and twelfth days—that is, 4 g. of sugar. This makes the tea and coffee more palatable. If no sugar is passed 15 g. of bread—i.e., 8 g. of sugar, are given in two doses. On the thirteenth and fourteenth days another 15 g. of bread are added, so that the patient gets four doses of 8 g. of bread at four meals. It is most important to divide the carbohydrate among as many meals as possible so as to spread the effect of the dose of sugar on the level of the blood sugar as much as possible. If the patient is doing well the bread is increased to 45 g., which is enough to keep most patients comfortable. If the amount of aceto-acetic acid is quite small, a mere trace, the butter is then increased in two doses of 25 g., watching the effect on the aceto-acetic acid reaction and sugar.

This makes a diet of: carbohydrates, 41; protein, 35·5; fats, 167·5; total calories, 1865, which for a man of 60 kilos is 31 per kilo. The protein is 0·57 per kilo. It is quite true that this represents a considerable degree of under-nutrition, but it seems to be quite enough to enable weight to be maintained and life to be enjoyed. I think that it is wiser not to try to test the tolerance any further at this stage, but at the end of each month, if all is well, the amount of bread can be increased by another 15 or 30 g. if it can be tolerated. This diet is enough to live on and do light work. If, as often happens, the patient passes sugar when he is tested with 15 or 30 g. of bread, he is put back and kept at a lower level for a further period.

Variations of the Routine Diet.

The addition of alcohol to the diet in these severe cases, as recommended by Leyton,[24] is worth a trial, as he has found that alcohol can be given without causing the excretion of sugar. Two ounces of absolute alcohol can be used in this way. The agar-agar and bran biscuits recommended by Allen are of great assistance to the patient, as they provide a medium for eating the butter.

The ladder diet which has developed from the original egg and vegetable day of von Noorden differs from Allen's diet in certain important details. The fast is not continued until the patient ceases to pass sugar, as we find that the patient stands the alternations of egg and vegetable days and fast days better than the prolonged fast. Allen has occasionally found that elderly people are upset by the fast and may have to be fed on the third and fourth days. The routine alternation which we use may explain why we have not noticed y ill-effects. Allen breaks the fast with increasing nts of vegetables and tests the carbohydrate tolerance a diet which contains very little protein and fat. Later increases the protein to 1·5 g. per kilo, and last of all the fat. This scheme is more elaborate than the ladder plan, but it is more complicated for ordinary people to carry out.

The question as to whether it is right to add carbohydrates first and thus test the carbohydrate tolerance, and then add protein, is a very important one and is opposed to our plan. Allen's recent work[18] on the conversion of a mild diabetes into a severe one is very important, as he found that it was much easier to lower the sugar tolerance of a dog by overfeeding with sugar than with starch, and with starch than with protein. Thus the recent work is opposed to the principle of adding carbohydrate first. The ladder plan, which was based on the old idea of avoidance of carbohydrates, appears therefore to be more scientific than Allen's plan. The danger of giving fat is two-fold: (1) It may cause an increased formation of acetone bodies, and the fat intake must be kept low, especially in severe cases; (2) fat has a very high caloric value, and by increasing the fat too much it is easy to break the first principle of the treatment and overfeed the patient. It is very difficult to determine whether the results are better with one plan or the other.

It has been suggested that one reason why the period of starvation produced such good results was that the absence of food allowed the pancreas to rest its external secretion and so improved the internal secretion. Allen[25] supported this suggestion, as he found that ligature of the pancreatic duct of a partially depancreatised dog who was excreting sugar caused the cessation or diminution of glycosuria. This evidence was very suggestive, but it has been shown by Homans[26] that the exclusion of the pancreatic juice from the intestines rendered it difficult for the animal to digest its food properly and it lost weight. Thus tying the pancreatic duct causes under-nutrition, and it is the under-nutrition, not the resting of the pancreas, which prevents the glycosuria.

The treatment of the patient who passes sugar as soon as food is given, in spite of repeated fasts, is very difficult. Unless all hope is abandoned of improving the condition it is better to persevere with a very small amount of vegetables, protein, and fat, adding a certain amount of alcohol. The outlook in a long-standing case of this severity is very bad, but in an early acute case the treatment should be persevered with for a considerable time, as the acute case sometimes makes a surprisingly good recovery.

Exercise in Treatment.

The question of the effect of exercise on the diabetic is a very important one, and Allen[27] has devoted a good deal of attention to it. It has been shown that exercise causes a diminution of glycosuria and hyperglycæmia in mild and perhaps moderately severe cases. In more severe cases, however, this is not the case, and sometimes an increase of glycosuria and hyperglycæmia occurs. Allen is strongly of the opinion that exercise is of great benefit to the general health of the patient.

My experience has caused me to express myself rather differently, and to draw a very sharp distinction between the treatment of the acute stage and of the convalescent stage. Our practice at St. Bartholomew's for some years has been to keep the patient strictly in bed so long as the sugar tolerance was being tested. This procedure was started originally by the sister of the ward, Miss Powell, as she realised that it was impossible to keep a watch over the patients when they were up and about in a general ward. Even when they are in bed they still occasionally acquire carbohydrate surreptitiously. Although the practice was started for this reason, it was soon realised that when the patient was on a diet of very low caloric value it was much better that he should be at rest in bed. The work of Joffe, Poulton and Ryffel[28] on the metabolism of a man who only took 2000 calories per day, or 34 calories per kilo, showed that if the man was taking exercise his energy consumption was just as great as that of a well-fed man, but when he was lying still his basal metabolism was very much less than that of a well-fed man.

If the diabetic learns to lie still in bed he will have a much lower basal metabolism than if he is up, and therefore will be able to live in comparative comfort on a low caloric diet. Last autumn, as a result of seeing the three acute cases which I described in Lecture II., I was more firmly convinced of the value of the method for another reason. If the hypothesis is correct that in an acute case serious damage has been done to the islands of Langerhans, it seems reasonable to suggest that the patient should be treated as if he had had a severe illness. Whether it is possible to influence the course of the disease in any way by keeping the patient at rest no one can yet say, but the practice is justifiable on general principles.

Therefore, if the patient is seen soon after the onset of symptoms he should be kept in bed for a considerable time.

My practice now is to keep the patient in bed for four weeks after he is able to take a diet of reasonable caloric value with about 40 g. of sugar, if that result can be attained. During these four weeks no attempt is made to increase the diet at all. If he is not able to take so high a diet he should be kept at a level at which he does not have to pass sugar for the same period. After that time has elapsed he is allowed to get up by degrees. If he remains sugar-free he should gradually take on more exercise, but should avoid hard work. This advice is easy to give, but very difficult for the labouring classes to carry out. It is important to impress on the patients who have to live on a diet of low caloric value that they must rest properly whenever they are able. When they are convalescent, exercise and fresh air is good for them, as for ordinary people, and a general improvement in health may improve the sugar tolerance.

Determinations of the blood sugar have added a great deal to our knowledge of diabetes and the question arises as to their value in the treatment of diabetes. In the diagnosis of the doubtful cases the estimation of a number of points on the curve after a dose of sugar has been given is of very great importance. By that means, as I have shown in Lecture II., it is possible to settle whether a patient belongs to the class of diabetes innocens or to that of mild true diabetes.

The estimation of an isolated point is, however, of very little value unless special precautions are taken. The figure for the blood sugar of the patient who has fasted some hours is of some assistance in determining the progress of the case, but may mislead the physician entirely unless precautions are taken. If the level of the blood sugar is between 0·15 and 0·18 in the fasting patient it is evidence that the blood sugar is not yet normal and that the islands of Langerhans are still overworked. If, however, the figure lies within normal limits the only information gained is the knowledge that the level of the blood sugar has sunk to normal 12 hours after the meal. It can tell the observer nothing about the response to sugar. In order to do this a dose of sugar must be given and the blood examined at intervals through the next two and three hours. The information gained by such a curve is often of value, but hardly compensates for the great amount of time taken in collecting the samples even though the time taken in estimating the samples is small. Moreover, if it is known that the patient is a true diabetic useful information can be gained by analysing the urine after a dose of sugar to see its effect.

Isolated blood sugar determination can never replace urine examination, for it is very important to know whether sugar is passed or not. When the patient goes out of hospital he should always be taught to examine his own urine. The old teaching was that it was unwise to allow him to test his own urine, as he would be frightened by the discovery of sugar. The modern view is that he should learn as much about his disease as possible and know whether he is taking too much carbohydrate or not. It is better to teach the patient to use Benedict's solution rather than Fehling's solution, as it is easier for him to learn.

When he leaves hospital it often becomes difficult for him to collect his urine. He is apt to test the urine which is passed on getting up in the morning; this urine is usually free from sugar and may mislead him. It is better to tell him to test his urine after the evening meal in which some carbohydrates have been eaten. Testing one sample after a meal is a much more delicate test than testing a mixed specimen.

After-treatment.

The after-treatment of the patient is most important, as it is very easy for the patient to lapse almost unconsciously, and he should be seen at regular intervals.

The treatment of minor or serious illness is a very difficult matter. The usual effect of illness is to make the patient pass sugar and the usual diet for a sick person contains a great deal of sugar. If much carbohydrate is given the islands will be much overworked, and even if the islands escape any damage from the nature of the illness the sugar tolerance may be seriously depressed. The diet should be of a low caloric value, but milk may have to be given, as the ordinary diet is repugnant to the patient. Alcohol should be of use in supplying caloric value. As soon as the illness is over starvation days should be resorted to and the diet gradually increased. Unfortunately, an illness often produces a permanent decrease in tolerance. Great attention should be paid to all minor ailments; boils and pyorrhœa and all sources of infection should be dealt with.

Causation and Treatment of Diabetic Coma.

I will pass now to consideration of the cause of diabetic coma and its treatment. Coma was one of the most dreaded complications of diabetes, but under modern conditions it should be very rarely seen. However, there will always be some diabetics who will die in coma, either because the disease is so acute or because the patient has refused to follow the treatment advised, or in those very advanced and severe cases when the choice lies between allowing the patient to die of under-nutrition or of coma. In the treatment of cases of diabetes it is necessary that the doctor should be able to make estimations of the amount of CO_2 in the alveolar air of the patient.

The most accurate methods are either Haldane and Priestley's[29] or Hasselbach's[30] method. For the clinician Fridericia's apparatus[31] is sufficient and by its use the observer can form some idea of the severity of the case. The usual figures for the alveolar CO_2 is 5·0 per cent. to 5·5 per cent. for men. In a severe diabetic it will fall to less than 3·0 per cent. In my experience this does not mean that the patient is going into coma at once, but that he is in a dangerous state. The man whom I have already mentioned had an alveolar CO_2 of 2·6 to 2·8 per cent. for many days. If the alveolar CO_2 falls below 2·0 per cent. the patient is very unlikely to recover. I have once seen a boy with only 1·8 per cent. who recovered. If the alveolar CO_2 was less than that figure death always ensued.

The determination of the amount of alveoli reserve in the blood by van Slyke's method is of great value, but is not so easily done as the alveolar CO_2.

Acetone, aceto-acetic acid, β-oxybutyric acid are excreted in the urine as a result of the incomplete combustion of fat, and all three substances have been considered at one time or another to be the cause of coma. There are still many misconceptions about these substances. Thus acetone is either absent from, or only present in very small amount in, freshly passed urine, and is formed as a break-down product of aceto-acetic acid—Embden and Schlich[32] and Folin.[33] The nitro-prusside test which Rothera made more sensitive by the addition of ammonium sulphate is a test for acetone in a dilution of 1 in 20,000, but is a much better test for aceto-acetic acid, as the latter can be detected in a dilution of 1 in 400,000. The ferric chloride test has a delicacy of 1 in 14,000, and Hurtley's test[34] has a delicacy of 1 in 50,000 for aceto-acetic acid. As acetone is only present in urine as a decomposition product of aceto-acetic acid it can hardly be the cause of coma. The evidence for and against aceto-acetic acid and β-oxybutyric acid must therefore be considered.

It was pointed out by Neubauer[35] that when the amounts of acetone bodies excreted were small, more aceto-acetic acid is present than β-oxybutyric acid, but as the total acetone bodies increased the percentage of the β-oxybutyric acid also increased until it formed 70 per cent. of the total. Kennaway[36] was able to confirm this from his results. Hurtley[23] also confirmed it, but preferred to express the results rather differently. He plotted on a table the percentage amount of aceto-acetic acid, which corresponded to each increase of 5 g. of β-oxybutyric acid in 7 cases. As the total acetone bodies increased the percentage of the aceto-acetic acid gradually fell to 30 per cent. or lower, but if the patient was near coma or in coma there was a rise in the percentage amount—in Joslin's case to 54-67 per cent. This point was one of several which led Hurtley to regard the aceto-acetic acid as the important factor.

Kennaway[37] has estimated the amount of aceto-acetic acid and β-oxybutyric acid in the blood of 13 patients who had died of coma. The amounts of aceto-acetic acid varied between 53 and 109 mgm. per cent., while the amount of β-oxybutyric acid varied between much wider limits—40 and 215 mgm. per cent.

These results suggest that the aceto-acetic acid is a much more poisonous substance than the β-oxybutyric acid, as the variations in the amount of aceto-acetic acid in the blood are so much smaller than those of the β-oxybutyric acid. Further, Geelmuyden[38] has shown that the liver contains much less acetone and much more β-oxybutyric acid than do the muscles, blood, brain, lung, and kidney. These results certainly suggest, as Hurtley pointed out, that the aceto-acetic acid is converted into β-oxybutyric acid in the liver.

The work of Hurtley and Trevan[39] has done much to establish the view that aceto-acetic acid is the cause of coma. They pointed out that sodium aceto-acetate and the allied compounds, ethyl aceto-acetate, acetyl acetone, and sodium salicylate, all contain the so-called enolic group. (Fig. 5.)

When acetyl acetone was injected into a cat the animal died within 40 minutes with all the symptoms of coma, deep breathing, &c. When any of the above substances were injected into a decerebrate cat with the posterior corpora quadrigemina intact hyperpnœa was produced. They suggested that the aceto-acetic acid did not produce any symptoms in virtue of its H-ion group, but because of the enolic group $\begin{matrix}\mathrm{COH}\\ \mathrm{CH}\end{matrix}$. β-oxybutyric acid has no enolic group and does not produce this effect. Trevan has continued this work and has shown that when an aceto-acetate is injected into a cat in neutral solution hyperpnœa (or air-hunger), coma, and a fall of blood pressure take place. These results occur, although the reaction of the blood is on the alkaline side of normal. The injection of an acid, such as hydrochloric acid, which will produce hyperpnœa, shifts the reaction of the blood slightly to the acid side. In Trevan's cats there was no decrease in the alkali reserve of the plasma, whereas that is always a marked feature of coma in man. He explains this difference by suggesting that whereas he injected a neutral solution the patient with severe diabetes forms aceto-acetic acid, which has to be neutralised. This work of Hurtley and Trevan, and its extension by Trevan, shows fairly conclusively that the chemical substance which causes diabetic coma is not β-oxybutyric acid, but aceto-acetic acid, and that it produces its effects not by its acid properties, but by virtue of the enolic grouping $\begin{matrix}\mathrm{COH}\\ \mathrm{CH}\end{matrix}$. This work explains why the injection of sodium bicarbonate is very unsatisfactory in the treatment of coma. The addition of the sodium bicarbonate adds to the alkali reserve of the plasma, and thus supplies an alkali which will be available to neutralise the aceto-acetic acid. But it cannot influence the poisonous action of the aceto-acetic acid. *This* is confirmed by an observation of Allen[40] who raised the alkali reserve of the plasma above normal without preventing the death of the patient in coma. It may well be asked whether administration of sodium bicarbonate to such patients is of any use if it cannot neutralise the poisonous effect of the aceto-acetic acid.

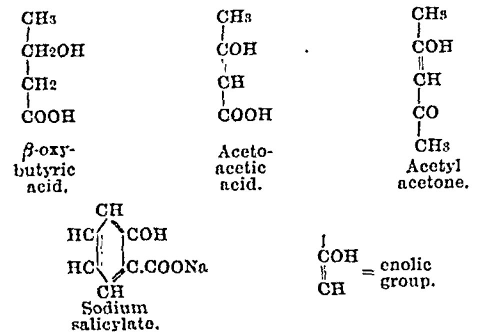

Fig. 5 shows the graphic formulæ of β-oxybutyric acid, aceto-acetic acid, acetyl acetone, and sodium salicylate.

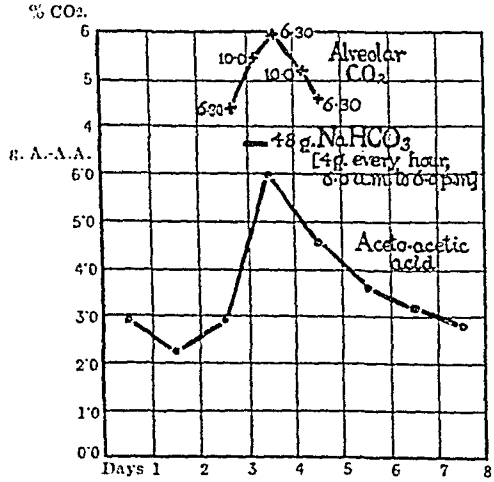

FIG. 6.—Showing effect of 48 g. $NaHCO_3$ on output of aceto-acetic acid and alveolar CO_2.

I think that it is correct treatment to give sodium bicarbonate to patients who are either on the verge of coma or in coma for two reasons: (1) to raise the alkali reserve of the blood if possible, so as to provide plenty alkali to neutralise the aceto-acetic acid which is constantly being formed; (2) to enable the neutralised aceto-acetic acid to be excreted more easily. I have made two experiments which bear on this last point. (Fig. 6.)

The first was made in 1915 on a case of severe diabetes who was doing fairly well at that time, as he was only passing 10 g. of sugar a day. The diet was constant throughout the experiment. The aceto-acetic acid output was between 2 and 3 g. a day. On the experimental day 4 g. of $NaHCO_3$ were given every hour from 6.0 A.M. to 6.0 P.M., making 48 g. in all. The aceto-acetic acid output was 6·0 g. on that day and did not return to its original level for another three days. The amount of CO_2 in the alveolar air was determined at 6.30 P.M. on the previous day and was 4·4 per cent.; at 10 A.M. on the experimental day it was 5·5 per cent.; at 6.30 P.M. it was 5·9 per cent. At 10 A.M. on the day after it was 5·2 per cent., but had fallen to 4·6 per cent. by 6.30 P.M. of that day. If no determinations of the alveolar CO_2 had been made it would have been possible to argue that there was an increased formation of the aceto-acetic acid, but, as there was a rise in the alveolar CO_2, it is fairly certain that more aceto-acetic acid was excreted in the urine.

I have repeated this on one other severe diabetic in a different manner. (Fig. 7.)

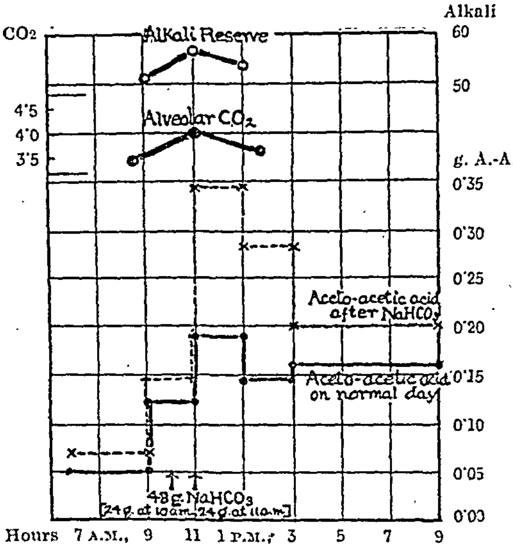

FIG. 7.—Showing effect of 48 g. $NaHCO_3$ on the excretion of aceto-acetic acid, alveolar CO_2, and alkali reserve.

The urine was collected in separate portions from 6 A.M. to 3 P.M. on two successive days. The diet given was identical, but the patient chose to add carbohydrate himself in the middle of the second day. He passed 1·5 *g.* and 2·6 *g.* of sugar per hour in the critical periods. The amount of aceto-acetic acid excreted per hour varied from hour to hour on the control day. On the experimental day 24 g. of $NaHCO_3$ was given at 10 A.M. and again at 11 A.M. The amount of aceto-acetic acid excreted was slightly greater, 0·125 to 0·145 between 9 and 11. Between 11 and 1 P.M. there was a much greater output, 0·19 to 0·345 g. From 1 to 3 the output of aceto-acetic acid was rather less, 0·155 to 0·28 g. During the four hours after the sodium bicarbonate, therefore, an extra 0·29 g. of aceto-acetic acid was excreted. The alveolar CO_2 rose from 3·4 at 9 A.M. to 4·0 per cent. at 11 P.M. and had fallen to 3·7 per cent. at 1.30 P.M. The alkali reserve rose from 51 vols. per cent. to 57 vols. per cent. at 11 P.M. and fell to 54 vols. per cent. at 1.30 P.M. The breaking of the diet on this day by the patient was peculiarly annoying, but the addition of carbohydrate is always thought to reduce the acetone bodies and can hardly increase them. The effect in this case is similar to that in the other, but whereas the extra aceto-acetic acid excreted in Case 1 was 3·0 g. on this occasion it was 0·6 g. The alkali reserve was not estimated in the first case but was within normal limits in the second case, and there was no real necessity for the giving of any alkali.

Whether the sodium bicarbonate acts by virtue of its alkaline action or by the fact that it supplies more base is uncertain. Patients have recovered from coma temporarily after normal saline solutions, just as well as after bicarbonate solutions. Allen makes a practice of giving plenty of sodium chloride to his ill patients and it may well be that the base is the important factor which is required. Therefore either sodium bicarbonate or sodium chloride should be given to cases in coma or on the verge of coma. If the patient is admitted on the verge of coma special attention must be paid to getting the bowels open. The patient should be made to drink plenty of fluid, beginning with one pint every hour, with or without 4 g. of sodium bicarbonate. No food should be given. If the patient is already in coma bleeding should be resorted to, and a big intravenous infusion of sodium bicarbonate or sodium chloride. Estimations of the alveolar CO_2 should be made two or three times a day, preferably by the Hesselbach method, as the patient is often too ill to assist the observer. These estimations enable the observer to form some idea of the severity of the disease and to watch the effect of treatment. If the coma has developed quite early in the disease great efforts should be made to keep the patient alive, as the very acute cases sometimes recover in a surprising manner. Nevertheless, patients in coma usually die.

CONCLUSION.

The account of the ætiology of diabetes which I have given shows how little we really know in spite of the great advance which has been made. Similarly, the treatment has been improved out of all knowledge since 1915, but the disease remains a dread disease. It is true that we prolong the life of the severe cases for several years, and during most of that time the patient feels comparatively well. Yet the treatment is in no sense of the word a real cure. The most that we hope to do at present is to arrest the disease, and in order to do that the dietetic restrictions must be severe and carried out with the coöperation of the patient.

In conclusion, I wish to express my thanks to all those who have helped me, especially to Sir Archibald Garrod for permission to investigate his patients and for much real assistance; to Dr. Hurtley for originally interesting me in this subject and for much assistance with the chemistry of the disease; and to Miss N. Powell, for many years the sister-in-charge of Sir Archibald Garrod's male ward, for her supervision of the patients and the assistance with the details of the diets.

A MENTAL HYGIENE LEAGUE.—There has recently been formed in France (99, Av. de la Bourdonnais, Paris vii.) a League for Mental Prophylaxis and Hygiene. The League proposes to study problems relating to the prevention of mental disorders and the preservation of a "psychic equilibrium" both in individuals and in groups. The care of mentally deficient children is receiving attention, and the League is also advocating the provision of early treatment clinics. At present these are designed as a part of the organisation of the existing asylums. It may well be that experience will show that they will be more successfully developed in connexion with general hospitals. The League is anxious to be brought into contact with organisations having similar aims in other lands.

THE NON-OPERATIVE TREATMENT OF SURGICAL TUBERCULOSIS.*

BY SIR HENRY GAUVAIN, M.A., M.D., M.C. CANTAB.,
MEDICAL SUPERINTENDENT, LORD MAYOR TRELOAR CRIPPLES' HOSPITAL AND COLLEGE, ALTON, HANTS; HONORARY CONSULTING SURGEON TO THE WELSH NATIONAL MEMORIAL ASSOCIATION FOR THE TREATMENT OF TUBERCULOSIS, ETC.

THE following remarks will be confined to tuberculous disease of the bones, joints, and glands, in which conditions non-operative treatment may now be adopted with confidence and a reasonable assurance of success. In certain other non-pulmonary tuberculous lesions—e.g., of the kidney—operative interference still has an essential field, while in such situations as the meninges of the brain treatment of any sort remains almost futile. Operative treatment of an active tuberculous lesion is based on a false pathology, except in cases where the lesion occurs in a situation where its presence is incompatible with life. It is the logical sequence to the "tuberculome" theory of surgical tuberculosis.

Lannelongue showed that the progressive extension of a tuberculous abscess towards the skin was not a mechanical phenomenon, but was the result of primary infection and subsequent excentric destruction of tissues by tuberculous elements advancing much as does a neoplasm. Hence there was evolved a radical treatment which arrived at the total extirpation of tuberculous tissues. This practice, possible and efficacious with small tuberculous foci, exposed the patient to serious danger when applied to extensive bony lesions. The mortality, both immediate and indirect, after major operations was appallingly high, and in the survivors, especially growing children, the extensive mutilations involved produced deplorable orthopædic results. Resection of the hip-joint and excision of the knee often left children sadly crippled, while in spinal caries the situation of the lesions made it usually impossible to excise all the bony tissues invaded by tuberculous disease. Improvements in surgical technique and in asepsis did much to reduce mortality, but even in the latest apology for radical treatment which I have seen, a paper read by Sir Harold Stiles at the annual meeting of the British Medical Association in 1912, the results compare most unfavourably—in spite of the writer's acknowledged pre-eminence as a surgeon—with those obtained by less daring but much safer conservative measures.

To the "tuberculome" theory just referred to the conservative surgeon opposes a theory based on the defensive resources of the patient. A tuberculous lesion provokes a reaction. There is the formation of a zone of resistance about the focus of the disease by the formation of fibrous tissue which encysts, limits, and tends to prevent the progress of invasion. Thus the issue is the result of two opposing forces—the disease which attacks the organism and the reaction which this attack provokes. It appears reasonable to reinforce this natural defence and diminish the virulence of the attack of the bacillus, limiting in this way its progress.

Spread of Conservative Treatment.

Fully to appreciate the change which has arisen in surgical opinion and policy, it would be desirable to sketch the evolution of ideas prevailing during the last 50 years, and such a study is indispensable for a correct appreciation of our views to-day. Time, unfortunately, does not permit that review, desirable though it undoubtedly is. Two reports, however, must be mentioned.

In 1903 Sir Anthony Bowlby demonstrated in the clearest possible manner the undesirability of radical treatment in tuberculous disease of the hip-joint when he delivered an address at Nottingham on 900 cases of tuberculous disease of the hip-joint, treated at the Alexandra Hospital, with a mortality of less than 4 per cent. This paper constitutes a landmark of the highest importance in the history of the treatment of surgical tuberculosis, and I would urge its careful perusal by all interested in the subject. His brilliant record was only possible by abstention from major operations in active tuberculous disease of the hip-joint and aseptic technique in such minor operations as were indicated. The other report to which I would refer is that of a discussion opened by Mr. A. H. Tubby in 1912 at the

---

* The opening paper delivered before the Medical Society of London on March 14th, 1921.

Royal Society of Medicine, which admirably expressed the more enlightened views lately prevailing, and made it clear that the leanings of surgeons generally were towards conservative as opposed to radical treatment. The value of treatment in the country was emphasised, though even as recently as 1912 the speeches reported at that discussion show that all that is implied by conservative treatment as I conceive it was still ill-understood. One speaker summarised the position in a sentence: "I look forward to the time when all these cases will be treated until they are well in convalescent homes in the country." I may here be permitted to interpose, that it is just these ill-equipped, inadequately staffed, and inefficient country homes which have done so much to discredit conservatism in treatment. Much more is required than they can supply, as I hope to show presently, and the hope for these patients in the future lies in up-to-date, well-equipped, properly staffed, efficient country hospitals as part of the scheme for the treatment of sufferers from surgical tuberculosis. It may not be without interest to recall that no inconsiderable part of the discussion was devoted to tuberculin treatment. Clinicians were then by no means greatly convinced of its value, nor does there appear to be an appreciable change in their attitude towards tuberculin to-day.

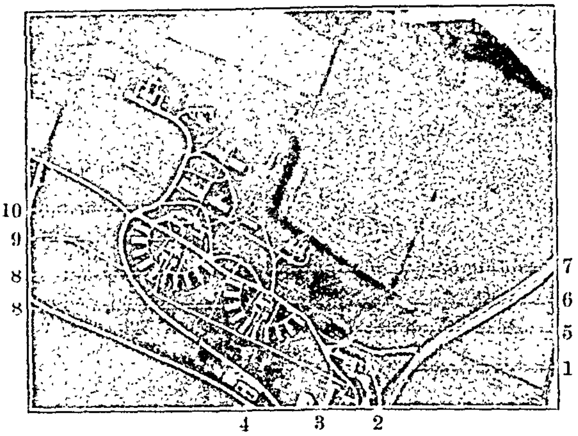

FIG. 1.—Treloar Cripples' Hospital, Alton, from the air. Photograph taken from an aeroplane flying at a height of 4500 feet above the hospital.

Queen Alexandra Nurses' Home. 8, 8. The 20 wards. 9. Outpatient department and treatment block. 10. The central kitchen.

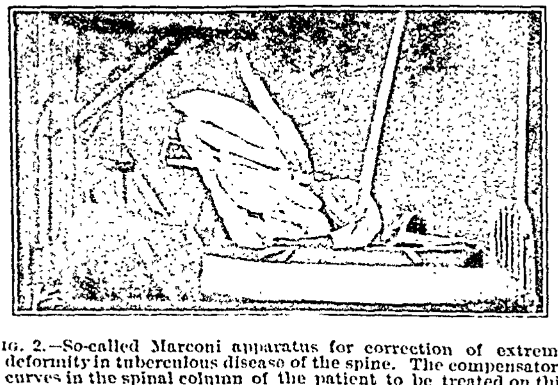

FIG. 2.—So-called Marconi apparatus for correction of extreme deformity in tuberculous disease of the spine. The compensatory curves in the spinal column of the patient to be treated on this apparatus are first straightened; the angular curvature can then be most effectively treated mechanically by traction on the head and pelvis and pressure on the deformity. Great care must be exercised, but extreme deformity is correctible or reducible by this method unless too firm ankylosis has taken place.

One point of great importance came out clearly: "tuberculous joint disease is arthritis occurring in a tuberculous patient, and is not merely a joint affection." This is the keynote of, and justification for, non-operative treatment of surgical tuberculosis. It needs the greatest possible emphasis, for even to this day there is too great a tendency to concentrate unduly on the local lesion and disregard the fact that the patient himself has contracted a general disease, of which any particular lesion or lesions are merely local manifestations.

Present Uses of Pure Surgery in Bone, Joint, and Gland Tubercle.

The title of this paper is perhaps hardly a satisfactory one. Pure surgery still plays a part in the treatment of bone, joint, and gland tubercle, though in cases of active disease a continually diminishing part.

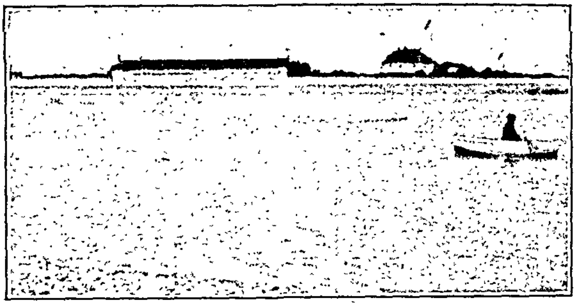

FIG. 1A.—Treloar Cripples' Hospital, Hayling, from the sea. Note the flat littoral, extensive beach, the proximity of the Pavilion to the sea, the absence of anything which could interfere with marine treatment. In addition, the situation has been carefully selected because of the bracing but equable marine climate, clearness of atmosphere and absence of mist, remoteness from rivers, abundant sunshine of high actinic value aided by the reflected light from the sea, protection from cold winds by the South Downs on the north, peculiarly low rainfall owing to physiographical conditions, sandy absorbent soil, remoteness from towns and absence of interference by seaside visitors, extensive beach in relation to area of land purchased, &c.

It is often justifiable in the extirpation of the smaller tuberculous lesions; it is occasionally permissible in such conditions as tuberculous disease of the knee-joint in adults where progress by conservative measures is slow and the time factor is of importance; it may be essential for the saving of life under increasingly rare circumstances in almost any situation of the body. It is again indispensable in the correction of ankylosed or other deformities where faulty initial treatment has permitted such deformities to arise—e.g., a hip-joint ankylosed in a bad position. It may be called for where faulty technique has resulted in secondary infection. But no striking advance has been made in the operative treatment of acute tuberculous bone and joint disease unless bone grafting of the carious spine be considered as such. That operation is, however, essentially a conservative measure. No attempt is made to deal with the lesion which calls for such an operation. It is simply an internal method of splinting the spine, designed as a substitute for the instrument maker's skill. In the majority of cases it is an unnecessary operation provided reasonable facilities are available for treating the patient; in certain cases it has distinct and considerable dangers; in a limited number of cases it presents certain advantages. It possesses one point in its favour in that it is a conservative operation; it is a tangible if tardy recognition of the fact that to immobilise a tuberculous lesion is a better way of promoting healing than to attempt its extirpation; but with increasing appreciation of the value and utilisation of properly applied conservative treatment the indications

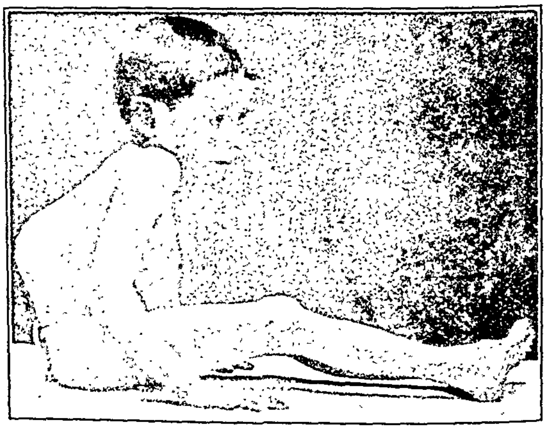

FIG. 3.—Patient suffering from extreme angular curvature of the spine, the result of tuberculous disease.

or the performance of this operation should be greatly educed, to the advantage of the patient. I would appreciate he operation more if it made cure certain where a purely non-operative method of treatment would have failed; but I cannot conceive that it would have saved the life of any one of my spinal caries cases who have died. It would have ncreased my mortality if generally adopted, and I think I can demonstrate that it would have made little appreciable difference in the length of treatment required.

Definition of Conservative Treatment.

The title "non-operative treatment" of surgical tuberculosis conveys no suggestion as to what the treatment if non-operative may be. Treatment, where operation is avoided in these conditions, is usually termed conservative. This term again is open to criticism. What is the conservative treatment of surgical tuberculosis?

As usually understood it conveys no very exact meaning. By some it has been confused with convalescent treatment, but there is a period of convalescence in the natural history of the disease in a patient whether he be treated conservatively or radically. Others regard conservative treatment as treatment without operation, but have no very clear ideas of what should be substituted for operation. May I explain what I understand by conservative treatment? I would define conservative treatment in surgical tuberculosis as the adoption of all measures which tend to improve the patient's general health, increase his powers of resistance to tuberculous disease, and preserve or restore the part or parts attacked, in contradistinction to radical treatment, which aims at the cure of the disease by the removal of the local lesion. It will be evident that such a definition is the very antithesis to lack of treatment, that it necessitates the employment of very active, numerous, and complicated methods, that it by no means necessarily implies exclusion of surgical interference, although surgery from being the one treatment becomes relegated to a very inferior but still useful position, as a possible aid to cure or amelioration under certain conditions. Moreover, I would give it a wider meaning than mere institutional treatment, and would not confine conservative treatment even solely to the application of merely medical or surgical care. There are means of improving the patient's condition, additional to those directly derived from the arts and science we practise, which possess an importance we have been slow to recognise. Chronic disease, which must of necessity involve lengthy treatment, has for too long been regarded from the purely pathological point of view. For this error blame must be ascribed to both the practitioner and the public. The former has narrowly concentrated on his own particular duties and disregarded the wider issues. The public has been content to leave the matter to the practitioner, and the intellectual and industrial aspect of the problem has been utterly ignored. The psychology and future well-being of the patient have been neglected, yet no one would deny their importance. A normal, healthy, well-cared-for, suitably occupied child is a happy child. He is given full play for natural healthy mental and physical activities. Conversely, it is of obvious assistance to the patient to make him happy and normal, and all means to that end should be encouraged and utilised. The monotony of immobilisation, of long-enforced recumbency, of fixation in unnatural attitudes cries for alleviation. Consider what such unnatural restrictions would mean to us, who have so many resources of our own to fall back upon, and what they must be when uncompensated. This state of affairs should have been remedied long ago.

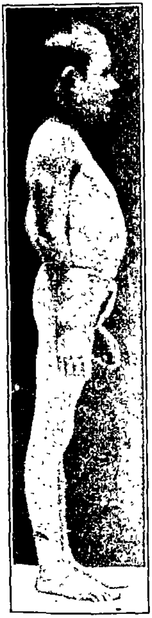

FIG. 4.—Same patient as Fig. 3, with the deformity largely reduced after treatment on the "Marconi." Further reduction of the deformity can now be obtained by using the "swinging back-door splint." (See THE LANCET, 1911, i., p. 568. Mechanical Treatment of Tuberculous Disease of the Spine.)

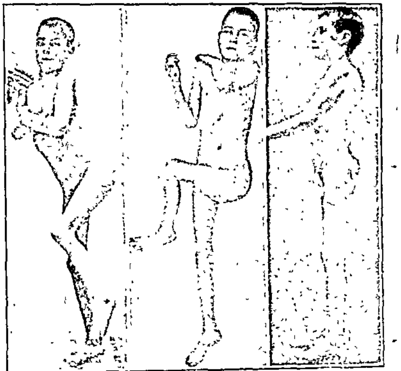
I may not pause to explain in detail how, but shortly, all child patients should be educated, and manual instruction should play a large part in the scheme, adolescents trained in work suited to their limitations, and adults occupied. In addition, all should be amused and entertained, and shown how to amuse and entertain themselves. The institutions at Alton and Hayling have been called the "happy hospitals." The secret of that happiness lies in the fact that the patients are as busy, as occupied, and therefore as happy and as contented as the staff. To assist in carrying out this part of the work we employ, on the educational side 14 trained teachers, and on the technical 5 trained instructors. This should be an essential branch of conservative treatment in every special institution for surgical tuberculosis.



5 6 7

FIG. 6.—Same patient photographed from above. This is a case of right-angled adduction, the most difficult deformity to correct in tuberculous disease of the hip-joint.

FIG. 7.—Same patient; treatment completed and deformity corrected.

Need for Prevention.

In any comprehensive scheme for the treatment of surgical tuberculosis prevention should play a much greater part than hitherto.

Much more should be done than is being done for the child with the stigmata of tuberculosis, the pre-tuberculous child, the offspring of tuberculous stock. I would advocate the establishment of properly equipped preventoriums where such children could have the benefit of preventive treatment under the best climatic, hygienic, dietetic, and educational conditions, and under skilled supervision. Such a preventorium is in contemplation at Alton, where it is anticipated it will be of especial value as demonstrating what may be accomplished on these lines. Non-residential open-air schools meet these needs to some extent, but they are necessarily imperfect, for the child returns nightly to unfavourable conditions.

Conservative Treatment of Tuberculous Abscesses of Bony Origin.

Conservative treatment includes consideration of general treatment, involving climatic, hygienic, dietetic, drug, educational, and other methods which it is desirable to employ, and local treatment, which is concerned with the correction or prevention of deformity and is largely orthopædic in character, but subject to those limitations enjoined by the fact that the patient is tuberculous. Under this heading may also be included those surgical measures which have still a place in treatment. To only one shall I here allude, and that is to the conservative treatment of tuberculous abscesses of bony origin.

I would state as a rule, to which there need scarcely be any exception, that tuberculous abscesses secondary to disease of the spine, hip, or, indeed, any of the larger bones or joints, should never be opened. Neither should they be left in the hope that they will be absorbed. As soon as

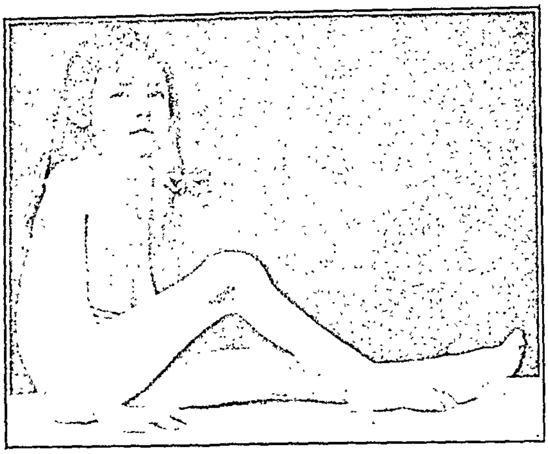

FIG. 8.—Tuberculous disease of the knee-joint, with subluxation of the tibia and sinus formation.

possible after their formation and as early in their evolution as the skill of the surgeon permits they should be aspirated. Occasionally their aspiration may be assisted by the employment of modifying fluids. The technique and arguments for the selection of this form of treatment, I, with my friend Dr. Jacques Calvé, have already fully detailed.

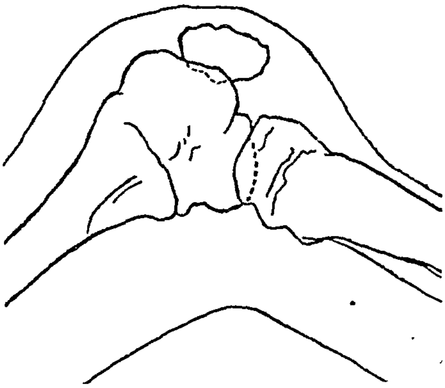

FIG. 10.—Tracing of skiagram of knee-joint of patient (Figs. 8 and 9 before treatment.

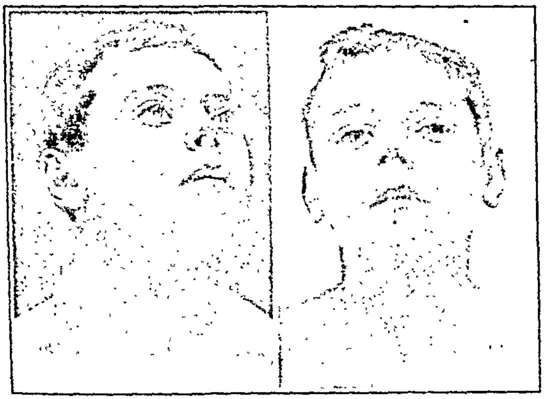
One point, often disregarded, is that the method of healing of a tuberculous abscess successfully aspirated is essentially different from that of a similar abscess which has been incised and has proceeded, as so often it does, to sinus formation. In the former case healing is centripetal, in the latter centrifugal. In the abscess skilfully aspirated the fluid contents are withdrawn, the abscess wall collapses, becomes denser, shrinks towards the causative lesion, continues to protect the organism from further spread of the disease, and becomes in time a mass of protective tissue, which gradually absorbs when no longer required. Incision of an abscess, on the other hand, necessarily increases the risk of dissemination of disease, and leaves a comparatively weak cicatrice probably infected with tubercle bacilli, which often tends to break down, perhaps years afterwards. Sinus formation then ensues, secondary infection frequently follows, healing is delayed and occurs in the reverse order to that succeeding aspiration—viz., from the causative lesion to



12 13

the surface. I do not think that anyone who has acquired skill and any considerable experience in the aspiration of tuberculous abscesses would ever willingly revert to their evacuation by incision. (See Figs. 21, 22.)

Adjuvant Treatment and Auxiliary Methods.

Adjuvant methods of treatment have largely increased in relative importance and scope of application in recent years, and represent perhaps the most interesting advances made in the non-operative treatment of surgical tuberculosis.

Amongst such aids are heliotherapy, balneotherapy, chemotherapy, vaccine treatment, and the therapeutic employment of X rays and other electrical agents. Auxiliary methods are of importance for the patient's general well-being, and are also often directly concerned with his disease; they comprise attention to the teeth, skin, throat, nose, ears, and eyes. These matters are frequently neglected, but demand attention and skilled care. I should also include under auxiliary methods of treatment a branch institution such as we are fortunate in being able to make use of, where chronic cases not requiring any special treatment may be detained indefinitely, and thus give room at the hospital for more acute patients urgently needing specialised care.

After-Care.

Lastly, I would touch on the all-important matter of after-care.

All patients who have suffered from surgical tuberculosis should have the continued advantage of occasional skilled supervision. No special hospital for the treatment of these conditions can be considered complete unless it possesses an out-patient department where discharged patients may be periodically examined, advised, and assisted. Not only is medical help required, but advice in the choice of occupation and assistance in obtaining suitable employment should be forthcoming. Associated with this department facilities are necessary for sending patients to open-air camps and holiday homes working in conjunction with, and under the management of, the parent institution. Many discharged patients at some time or other need such "toning-up" as these offshoots from the hospital can supply. Some cachectic cases, indeed, though not suffering from active tubercle, urgently require prolonged detention in residential open-air institutions, with the possibly ultimate transference to a residential technical school, such as the college for permanently crippled boys we maintain at Alton. Here lads between the age of 14 and 18 are admitted, detained for three years, trained in a trade suited to their limitations, and continue their general education during this period of training.

Conclusion.

All the methods of treatment I have just indicated are undertaken at the Treloar Cripples' Hospital and College at Alton and Hayling Island, and it is on experience gained there that I base my remarks. There is great hope for the future. The treatment of surgical tuberculosis has now aroused lay as well as medical interest. Active Government measures are being taken to combat the disease. Municipalities are devising schemes of their own under expert advise and with Government subsidy. If the spirit of the voluntary institutions can be maintained this is all to the good. Many medical men are exerting their powerful influence to promote reform. Prominent amongst these I would mention Sir Robert Jones, long a distinguished practitioner of conservative treatment, who advocates orthopædic centres in every locality. The desirability of associating cases of surgical tuberculosis with general orthopædic work may be criticised, but every medical man will support and sympathise with the efforts he is making. My experience is that it is quite fallacious to suppose that adults do not respond well to conservative treatment. It is of equal importance in adult cases of tuberculous disease, and yields equally gratifying results, although with adults there may be a more frequent necessity for operative aid.

FIG. 19.—Ambulant patients at Hayling Island enjoying sun, sea and sand—valuable adjuncts to the cure.

I have contented myself by referring simply to the general principles underlying the conservative treatment of surgical tuberculous affections. It is a method involving minute attention to detail. Any individual case may require the application of numerous measures appropriate to its peculiar requirements and varying according to the stage of the disease or even to the idiosyncrasies of the patient. To discuss these various forms of non-operative treatment summed up in the word conservative, the indications for their individual or combined employment, the extent to which they may

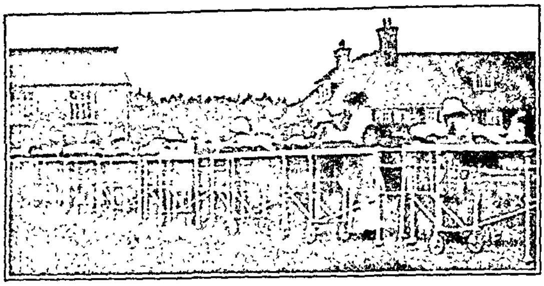

FIG. 20.—Patients suffering from spinal caries on specially designed spinal stands receiving sun treatment at Alton. All patients are educated while receiving treatment, and the illustration shows a teacher giving instruction while insolation is proceeding.

be usefully adopted, the effects which they separately or in combination produce, and the ultimate results which may be reasonably anticipated, is obviously impossible. The final judgment to be passed on any method of treatment must depend on the end-results achieved. Accordingly, I would refer the reader to the accompanying illustrations and tables of results, which will convey more graphically than any words the significance and value of conservatism in the treatment of surgical tuberculosis.

TABLE I.—*Results of Treatment.*

Lesion.	Admissions.	Discharged.	Disease arrested.	Improved.	Unimproved.	Removed or transferred.	Died.	Average stay in days.	Mortality percentage.
Spine	920	810	674	22	24	68	27	503·2	3·39
Hip	880	768	710	18	2	25	13	403·1	1·71
Knee	333	304	282	6	—	11	7	334·7	2·3
Other	354	315	265	16	5	19	9	259·8	2·8
	2487	2197	1931	62	31	123	56	416	2·54

Table I. gives an analysis of results of treatment of patients suffering from surgical tuberculosis at the Lord Mayor Treloar Cripples' Hospital, Alton, Hants, from the opening of the hospital in September, 1908, to Jan. 31st, 1921. Cases sent in as tuberculous but ascertained after admission not to be suffering from tuberculous disease—e.g., pseudo-coxalgia sent in as tuberculous disease of the hip-joint—are not included in Table I. Patients are classified according to their principal lesion. A very large number were suffering from, and in some cases developed during treatment, other or multiple lesions. In these statistics no mention is made of septic cases. The proportion of septic cases admitted is, unfortunately, a high one. The majority of those discharged unimproved were septic cases. By "disease arrested" is meant that the disease appears to be cured, abscesses are absent, sinuses healed, and the patient fit to return home and resume ordinary life, not under continuous supervision, but advised, where feasible, to report to our London out-patient department periodically for observation. Patients removed are those withdrawn by parents or guardians before the disease is arrested. Patients transferred include boys transferred direct to the College for technical training, or to an auxiliary home for protracted treatment. No death has occurred in the College. A certain number of patients have also been transferred to other institutions who required treatment of other conditions more urgently than continued treatment for surgical tuberculosis.

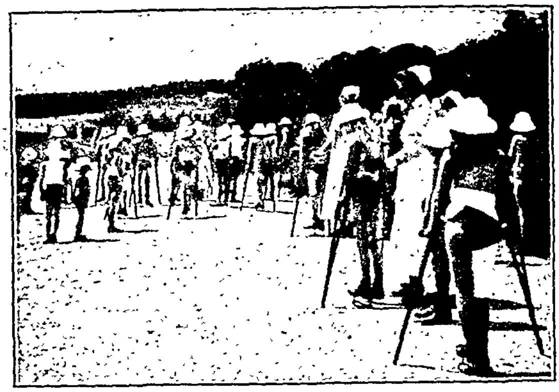

FIG. 20A.—Ambulant patients leaving the wards for nature study and sun treatment at Alton.

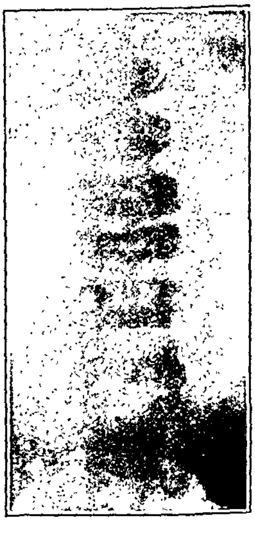

FIG. 22.—The same case later. All that is left of the abscess is the small particle of calcareous pus indicated by the white line at A. (Skiagram taken from above.)

TABLE II.—*Analysis of Mortality Statistics.*

Cause of death.	Spine	Hip	Knee.	Ankle.	Multiple.	Other.	Total
Meningitis.	13	6	4	2	—	1	26
Sepsis	8	6	1	—	2	1	18
Miliary tubercle...	1	—	—	—	1	—	2
Cerebral abscess	1	—	—	—	—	—	1
Intercurrent ...	4	—	3	—	1	1	9
—	27	12	8	2	4	3	55

It will be seen from Table II. that if we exclude patients who died from intercurrent disease the number of deaths directly due to tuberculous disease is reduced to 47, or barely over 2 per cent. of patients discharged. While meningitis is the commonest terminal cause of death, a certain number of these cases were septic as well as tuberculous, and I would regard secondary infection as the most serious complication which may arise. It may almost always be avoided if non-operative treatment is undertaken. Spinal caries is not only the commonest, but also the most fatal form of surgical tubercle admitted. It is noteworthy that 10 of the 13 patients suffering from spinal caries who died of meningitis were under the age of 5 years, and in many cases death occurred within a comparatively short time after admission. Contrary to what is frequently assumed by the public, surgical tuberculosis is more difficult to treat, more likely to produce considerable physical disability, and undoubtedly more fatal in the very young than in older children. Of all bony lesions the one I regard as most dangerous is tuberculous disease involving the flat bones of the skull.

SPINAL CARIES IN CHILDREN.

A METHOD OF FIXATION.

BY W. T. GORDON PUGH, M.D., B.S. LOND.,
MEDICAL SUPERINTENDENT, QUEEN MARY'S HOSPITAL, CARSHALTON.

THE appliances most generally used in this country in the treatment of spinal caries in an active stage are, so far as one can judge from the cases admitted to Queen Mary's Hospital, Carshalton, the Whitman stretcher, the double Thomas splint, the Berck tray, the plaster bed and the recumbent plaster jacket, and less commonly the spinal board, the Bradford frame, and the Phelps box. All these have features which recommend them, and all have imperfections the importance of which is more readily realised when the disease is treated on a large scale, as it is at Carshalton.

Drawbacks common to all are that the straps and buckles which restrain the patient are within his reach; thus recumbency is often by no means complete, and supervision may become a constant strain. While the spine is being treated other parts of the body are apt to suffer from the immobilisation; the chest often becomes flattened, and if the patient is long recumbent considerable wasting of the muscles of the lower limbs occurs from disuse, and the knee-joints may become lax and over-extended. In some cases there is slight contracture of the tendo Achillis owing to dropping of the feet, even though a cradle has been used to take away the weight of the bedclothes. The resulting inability to dorsiflex the ankles beyond the right angle produces for a time an awkward gait, and may lead to some degree of talipes valgus. Another drawback met with in some appliances is that there is no satisfactory arrangement for the use of the bedpan; further, portability is often limited, and even the more portable appliances are not very convenient to move more than a short distance.

Apparatus Used at Carshalton.

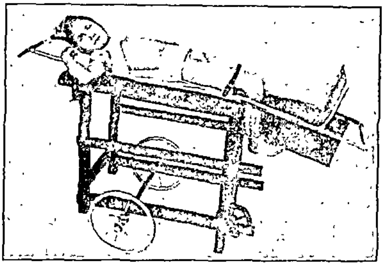
The apparatus which I use at Carshalton is a frame which rests on a carriage of simple design; the latter is not essential to the frame, which with its head end resting on a block acts equally well on a bed.

The frame, like the Whitman stretcher, is made of gaspipe and is generally eight or ten inches longer than the patient; it has a flat transverse bar opposite the shoulders and a padded one just above the knees. It is slightly narrower than the distance between the iliac crests, but from the lower part of the thighs is cranked out an inch and a half on each side to allow of more freedom of movement for the legs. It may be conveniently described from the foot upwards. An adjustable felt-lined foot-rest prevents the feet from dropping, and a bend in the frame at the level of the knees allows the latter to assume their natural position of rest in slight flexion. The thighs at their lower end rest on the padded crossbar to which knee-straps are attached by means of a saddler's D. (Fig. 2.) The legs lie on a felt-covered wooden flap, which can be dropped at suitable intervals to allow of active exercise of the thigh and leg muscles, the separate strap over each knee ensuring that this movement takes place without disturbance of the spine by the psoas. (Fig. 1.) To avoid the foot-rest when raising the legs the child has to dorsiflex his feet and thus a full range of movement at the ankle-joint is maintained. A flap beneath the buttocks allows of the use of an enamelled tray, 10" × 7" × 3," as a bedpan; if the frame is on a carriage the tray is suspended from the tubing by a special holder, otherwise it rests on the bed. (Fig. 2.) This flap, three or four inches wide, is made of duralumin; one border is curled closely round the tubing and serves as a hinge; the free end rests on a flat catch inserted in the tubing, and has a slot through which the catch slips if rotated, and thus the flap can be made to drop. If a child has enuresis the enamelled tray may be left under him with the flap in position to support the buttocks, and wetting of the bedding may in this way be avoided.

The "apron" consists of two transverse pieces of crash towelling connected by a duralumin rod on each side. The chest-piece is shaped to avoid the neck and sends a process over each shoulder, which ends in a webbing loop; at the side it passes beneath the armpit to end in a narrow pocket or hem in which the rod fits. The pelvis-piece which ends in similar pockets runs across the lower abdomen not extending lower than the level of the top of the intergluteal fold, which is the upper limit of the duralumin flap beneath the buttocks. Through slots in the shoulder bar and three holes in each connecting rod the apron is laced behind the frame with blind cord, the ends of which are tied to the foot of the frame out of the patient's reach. Compression of the front of the chest is thus avoided, although some flattening of the ribs behind may occur when a child is kept lying for a prolonged period.

If the prominence is moderate and not sharp the child can, as a rule, lie on a crash or leather cover, conveniently made taut by inserting duralumin rods in the side hems and drawing these together with a couple of webbing straps beneath the frame, which is bent at the hump to secure hyperextension. If the prominence is marked or so sharp that the skin is likely to be injured the child is made to lie on a thin plaster bed instead of a cover. The plaster bed is readily made by placing the child on his face in the hyperextended position and running plaster bandages up and down over the back between the scapular spines and lower sacrum, subsequently strengthening the bed with celluloid solution. Several inspections of the back are advisable during the first week, but after that it is unnecessary to remove the patient more often than once a month, when the opportunity is taken of placing a few squares of Gamgee tissue beneath the prominence with a view to a gradual correction of the deformity. As the correction obtained calls for it a new plaster bed is made

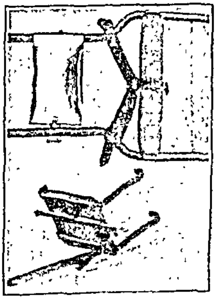
FIG. 1.



In high dorsal caries the frame is bent backward instead of forward at its upper end and the plate on which the head rests is domed downwards to allow of hyperextension; in cervical caries a leather collar is added to prevent rotation of the head. The children are provided with hand mirrors so that they can observe what is going on around them. Between head-plate and shoulder-bar there is a clear interval through which crumbs can fall.

The carriage is short, extending only from the shoulders to the knees; it is 30 inches high and consists of four deal uprights joined by side and end rails; it is supported by wheels, and hinged to it on each side is a narrow table on which the child rests his arms and places his toys, school books, or eating utensils. The clothing consists of vest and nightgown open at the back along their whole length, and between them a jersey open behind to within 3 inches of the neck. In mild weather stockings are worn, but in winter the legs are enclosed in a bag made of old blanket material; a broad binder is wrapped round the pelvis and thighs and a waistcoat shaped to enclose the shoulders round the chest, both being made of the blanketing and enclosing the frame. A cot sheet, blankets, and counterpane complete the bedding. No difficulty has been experienced in keeping patients thus equipped out in the open air on their carriages day and night throughout the winter months. The frame can be readily unclamped from the carriage for transference to a bed..

FIG. 2.



Showing buttock-flap, knee-bar, and pan-holder (from below).

Although somewhat complicated for purposes of description the apparatus is not difficult to measure for, make, or apply. It is made in the hospital workshop at a cost which compares favourably with that of several less effective appliances. With slight modification it is used in the treatment of hip disease.

THE ACTION OF
DIGITALIS AND ATROPINE ON THE PERIPHERAL BLOOD PRESSURE.

BY I. HARRIS, M.D., L.R.C.P., L.R.C.S. EDIN.,
HONORARY PHYSICIAN, CARDIOGRAPHIC DEPARTMENT, NORTHERN HOSPITAL, LIVERPOOL.

IN this paper the action of digitalis and atropine on the peripheral circulation has been studied, and from the relation between blood pressure and pulse frequency certain deductions have been made with regard to the influence of these drugs on the general circulation. The leading idea of the paper is to make the output of the single contraction a sort of criterion by which the effects of these drugs are to be gauged. It is assumed that a large systolic output will give rise to a correspondingly large pulse-pressure reading and vice versa. (The duration of the systole is taken into consideration.) The observation was conducted at the heart clinic of the Northern Hospital, Liverpool. Digitalis was prescribed, and blood pressure and pulse tracings were taken before the administration of the drug and once weekly whilst the patient was under its influence.

Procedure with Atropine.

With atropine the following procedure was adopted. The drug was administered hypodermically, the blood pressure and a cardiogram being taken before and half-hourly after administration. In some cases continuous polygraphic tracings were taken for from an hour and a half to two hours while the patient was under the influence of the drug.

Method of observation.—The combined palpation and auditory method was used to determine the systolic pressure, whilst for the diastolic I depended on the auditory method alone.

Systolic pressure.—Until a few years ago, it was generally assumed that digitalis increased the arterial blood pressure even if administered in therapeutic doses. More recently it has been observed that digitalis given in therapeutic doses does not increase the pressure. My experience was as follows: Soon after digitalis was administered an increase of pressure took place in the majority of cases, lasting a comparatively short period, after which it gradually fell, reaching a level considerably lower than before the administration of this drug. In some instances the declining curve does not show a straight downward line, but here and there a sudden rise is observable. This is often found in cases where digitalis has been administered for a lengthy period.

Diastolic pressure.—The gradual fall of the diastolic pressure owing to the action of the drug is far more pronounced than has been the case with the systolic. Now and then a slight increase is observable immediately after the administration of digitalis, or even in the latter stages, in cases where the systolic increase is pronounced. As a rule, however, digitalis effects a gradual decline in the diastolic pressure from the very commencement.

Pulse pressure.—The pulse-pressure curves show in the majority of cases a tendency towards an upward movement for a considerable time, after which they begin to decline.

The pulse pressure continues to increase at a time when both the systolic and diastolic pressure are on the decrease; the two latter pressures may fall considerably below the level at which they have been before the administration of the drug, yet the pulse pressure may continue to rise.

Pulse-rate.—Soon after the administration of digitalis the pulse rate often becomes lower, but later on for a longer or shorter period it keeps on very much the same level as before the administration of the drug, after which it becomes accelerated. Whilst it is true that soon after the administration of digitalis the systolic pressure is often raised and the pulse frequency diminished, no absolute interdependence between these two factors is demonstrable. In some instances a slowing of the pulse-rate is observable without any corresponding increase in blood pressure, and vice versa.

Relation of pulse pressure to systolic pressure and pulse frequency in hearts unaffected by drugs and those under the influence of digitalis.—In hearts unaffected by drugs the pulse pressure and pulse frequency stand, as a rule, in a definite relation to the systolic pressure. The higher the systolic pressure the higher the pulse pressure and vice versa. Thus in a typical case of senile heart the systolic pressure is raised and pulse pressure is correspondingly high, whilst in the normal heart, or in uncomplicated mitral disease, the systolic pressure is not raised and the pulse pressure is small. The pulse-rate, too, more often than not bears a certain relation to the systolic pressure in hearts unaffected by drugs. As a rule, a low pulse frequency is accompanied by a high pulse and systolic pressure, and the duration of the systole bears a certain relation to the pulse pressure, a long systole being generally correlated to a high pulse pressure and vice versa. The systole in a senile heart or in heart-block is distinctly longer than in a normally beating heart, and the pulse pressure is correspondingly high in these instances. These relations are completely altered by the action of digitalis. Under digitalis we often find a high pulse pressure in conjunction with a high pulse frequency, a short systole and a low systolic pressure.

Atropine: Action of atropine on cases unaffected by other drugs.—Within half an hour after the hypodermic injection of 1/100-1/75 of a grain of atropine, in the majority of cases under observation, the systolic pressure fell and the pulse pressure became diminished; the diastolic pressure, too, fell, but to a lesser degree than the systolic, and the pulse-rate became lower. Usually, as we have seen, a low pulse-frequency is correlated to a high systolic and pulse pressure. Under the influence of this drug, in doses indicated above, both these pressures became low.

Action of atropine on cases previously under the influence of digitalis.—In all essentials the effect of atropine in doses indicated above is the same whether the patient has been under the influence of digitalis or not. The systolic and pulse pressure become lower and the pulse frequency also becomes lower. If the pulse frequency has increased owing to the action of digitalis, the administration of atropine will considerably lower the pulse-rate. Similarly under atropine any cardiographic evidence of digitalis poisoning which may be present will disappear.

Action of atropine in doses of 1/50 gr.—Atropine in doses of 1/50 gr. increases the pulse frequency, the systolic pressure becomes lower under its influence and the pulse pressure diminished.

Contrast in effect of digitalis and atropine action.—Under digitalis a high pulse pressure is found in conjunction with a high pulse frequency, a short systole, and a low systolic pressure. Under atropine in doses of 1/100-1/75 gr. a low pulse pressure is correlated to a slow pulse with a relatively long diastole and a low systolic pressure.

Discussion.

We have seen how, after a comparatively short period, the systolic pressure falls and the pulse pressure increases. The fall of the former is obviously due to the low diastolic tension, which we have seen is one of the characteristic features of digitalis action. Now, the pulse pressure represents the output of a single systole; a high pulse pressure therefore means a correspondingly large output (the duration of the systole being taken into account). As the pulse frequency is not diminished but often increased, it follows that the total output of the heart per a given time is increased under digitalis. Even where the pulse pressure is not increased, since the pulse-rate is often increased, the total output would still be greater than normal.

Abnormal Lowering of Systolic and Diastolic Pressures.

The question now arises, Why are the systolic and diastolic pressures lower than normal when they ought to be higher, since the arteries receive more blood into them from the ventricles per given time than before the action of digitalis becomes effective? There are two possible explanations of this apparently paradoxical phenomenon. It is conceivable that dilatation of the arteries might cause a fall in the systolic pressure, although the total amount of blood they contain is increased. This does not seem a very plausible explanation. First of all, there is no evidence that under the influence of digitalis dilatation of the vessels takes place; on the contrary, all evidence points the other way. Digitoxin contracts all vessels, whilst digitalin contracts the vessels of the abdominal organs and dilates the vessels of the extremities[1]; the action of digitalis accordingly cannot result in fall of pressure, owing to dilatation of the arteries. Moreover, if dilatation of the vessels were the correct explanation of the fall of pressure under digitalis, it would still have to be assumed that with the increased output which the drug effects the blood accumulates on the side of the arterial circulation. This is an improbable assumption. Whence does the heart derive the blood for an increased output? From the reserve volume which remains normally in the ventricles after systole? This would soon be exhausted. From the veins? On the one hand we are supposed to have a piling up of blood on the arterial side; on the other hand, we have an ever-increasing output of the heart, the supply of which can only be derived from the veins. In other words, the veins, relatively at any rate, would receive less blood from arteries and give up more than is normally the case. Such double factors acting even in inconsiderable quantities would in a very short time completely empty the veins of their contents, when one considers the number of beats per 24 hours, and the fixed quantity of blood contained in the circulation. The theory that digitalis takes blood from the veins and piles it up on the arterial side seems to be accordingly untenable; it is extremely unlikely that the fall of pressure under digitalis is due to dilatation of vessels.

---

[1] Cushny: The Action of Drugs.

There is only one alternative explanation. The flow of blood in the vessels might take place at an accelerated rate owing to the influence of digitalis. Under these circumstances it is conceivable that the blood might leave the arterial system at a quicker rate than is normally the case. The increase of the output of the single contraction might not compensate adequately the accelerated rate of outflow of the fluid from the arteries. The total amount of blood contained in the arterial system per given time would accordingly be less than normal. The diastolic pressure would become low under such conditions, and incidentally also the systolic.

Increased Heart Content of Blood Caused by Administration of Digitalis.

That the flow of blood under the influence of digitalis is accelerated has long been proven.[2] But now comes the most interesting feature of the whole problem. A given volume of fluid which circulates in a closed system at the same rate at every part will contain exactly the same amount of fluid in all its parts per given time, whether the rate of flow is slow or quick, since the volume of fluid which leaves one side of the system is replaced by exactly the same amount of an inflow from the other. If the total quantity of blood per given time is to be diminished in the arterial system owing to the accelerated rate by which the outflow takes place, it must be assumed that the inflow takes place at a slower rate or in a decreased volume. This would presuppose that at another part of the circulatory system the quantity of blood is greater and the pressure higher than normal.

Which part of the circulation is thus affected? Not the venous side of the circulation to be sure. A cursory glance at the veins of a patient who is under digitalis is sufficient to convince oneself that the pressure in them is not increased and that the quantity of blood they contain is not larger than normally. We are driven to the conclusion that the only part of the circulatory system which could possibly contain a greater quantity of blood than normal owing to the influence of digitalis is the heart. As a matter of fact, the following consideration will show that it could not be otherwise. Supposing that under the influence of digitalis the pulse-rate, as it often does, remains the same as before the drug has been administered, the duration of diastole, to put it at the lowest—indeed, the duration of all phases of the heart—is the same under digitalis as before. But the flow of blood is accelerated. In the same time unit the heart will receive a greater quantity of blood than before the action of the drug. On the other hand, the outflow from the heart is not accelerated, since, as we have seen, the diastole in this instance remains of the same duration. The heart, therefore, will contain at the beginning of the systole a larger quantity of blood than under normal conditions. It is true, too, the output per single contraction is increased. It is also possible that soon after the administration the total amount of blood on the arterial side is increased. It is more probable, however, that the total amount of blood in the arteries is at no time augmented, and the increase in the systolic pressure, often observable soon after the administration of digitalis, is generally assumed to be due to contraction of the blood-vessels. But as the rate of the blood stream quickens under the influence of the drug the vessels give a greater volume of blood to the heart than they receive from it; the result is a fall of the arterial pressure and a rise in the intracardiac pressure. The angina-like pain from which patients suffer who are under the influence of an overdose of this drug and the fatal issue which sometimes, though rarely, attends its use, is to be attributed to high intracardiac pressure.

We see the action of digitalis does not effect, as is generally held, a diminution of blood on the venous side and a piling up of the fluid on the arterial side of the circulation. The true facts are different. The action of digitalis brings about a diminution of the quantity of blood in the peripheral circulation and a piling up of the fluid in the heart's cavities.

Cases 1, 2, 3, 5, 6, digitalis xv., thrice daily. Case 4, C. Case 7, digitalis xv.

BP, blood pressure. S, systole. D, diastole. P, pulse pressure.

The figures in the first line of each case represent readings taken just before digitalis was administered.

It is a common occurrence to observe a sudden rise in the systolic pressure after the patient has been for some weeks under the influence of the drug. Possibly this rise is in the nature of a reaction to the condition of the circulation, brought about by digitalis and not to the direct action of the drug.

* These cases have been under the influence of digitalis. † A case of auricular fibrillation. ‡ Some cases did not react to atropine.

Quickening of the Pulse-rate Resulting from Action of Digitalis.

Once it is recognised that owing to the action of digitalis the volume of blood in the heart's cavities is augmented, another feature in connexion with the action of digitalis becomes comprehensible, which otherwise would remain unexplained. It is a well-known fact, to which I have already referred in this paper, that the pulse frequency increases if digitalis is pushed long enough. Paralysis of the vagus is the orthodox explanation of this phenomenon. This explanation is unsatisfactory. I pointed out somewhere else that the dose of digitalis required to bring about an acceleration of the pulse-rate stands in a definite relation to the condition of the myocardium. If the latter is affected a small dose of digitalis is sufficient to bring about a quickening of the pulse-rate. It is difficult to understand why the vagus should so much more easily be paralysed when the heart muscle is diseased. As a matter of fact, as will be seen later on, there is ample evidence to show that the vagus function is not impaired at the time when acceleration of the pulse-rate takes place. To what, then, is the frequency of the heart's action due?

---

[2] Gottlieb and Magnus: Archiv für Experimentelle Pathologie und Pharmakologie, xlvii. Edmund: American Journal of Physiology, xviii.

It is generally assumed that the endocardium is endowed with an apparatus, stimulation of which is the exciting cause of the systole. The volume of blood in the heart's cavities has a good deal to do with the bringing about of a systolic contraction. It is obvious that if the cavities of the heart are filling up at an accelerated rate a volume of blood sufficient to excite a systolic contraction will accumulate in a shorter period of time than is normally the case. In other words, the pulse will become accelerated. No doubt digitalis acts also on the inhibitory apparatus, but the longer the patient has been under the influence of the drug the higher the rate of acceleration of the flow of the blood through the vessels. Soon a condition will be reached which overbalances its inhibitory effect. We see it actually happening in Case 1, Table I. Digitalis first effected an increase in pulse pressure. When the patient was kept under this drug for another week no further increase in blood pressure was recordable, but a pronounced acceleration in the pulse frequency took place instead. A further increase in pulse pressure was evidently impossible in this case, simply because as soon as the intracardiac pressure reached a certain height it excited systolic contraction.

The slowing of the pulse-rate brought about by atropine is evidently due to vagus stimulation. Apparently 1/100-1/75 gr. of atropine is not strong enough a dose to effect paralysis of the vagus endings. We know vagus stimulation lowers the output of the heart; hence the smallness of the pulse pressure. The intracardiac pressure will be diminished under these conditions, owing to the feebler contraction. The latter circumstance would explain why the cardiographic signs which are attributable to a high intracardiac pressure disappear under this drug. We have seen that in cases which, under the influence of digitalis, have exhibited an accelerated pulse frequency an injection of atropine effects a lowering of pulse frequency. Evidently the vagus function remains unimpaired, in these circumstances, as otherwise this nerve would not react to stimulation.

Atropine in doses of 1/50 gr. evidently paralyses the vagus ending, the pulse-rate is increased, the duration of the diastole being shorter than normal, the heart would not completely fill itself as is normally the case; the output per single beat would accordingly decrease, and one would get a relatively small pulse pressure under the circumstances. Evidently the total output of the heart under atropine is less than normal, otherwise we would be unable to explain the fall in the systolic pressure.

Summary and Conclusion.

Under the influence of digitalis the diastolic pressure becomes lower and incidentally the systolic, whilst pulse pressure rises. The decline of the diastolic pressure is not due to a diminished output of the heart—the contrary is the case. The low diastolic pressure is neither due to dilatation of the arteries. The conclusion is that the blood stream leaves the arterial circulation at a greater rate than under normal conditions. The corollary to this conclusion is that under digitalis the heart contains at the beginning of the systole a greater amount of blood than before. The quickening of the pulse observed in the latter stages of digitalis is due to the fact that in a shorter time than normal the intracardiac pressure is sufficiently high to excite contraction.

THE X RAY APPEARANCES OF SO-CALLED OSTEO-ARTHRITIS OF THE SPINE.

BY CLAUDE GOULDESBROUGH, M.A., M.B., B.CH. OXON., M.R.C.S., L.R.C.P. LOND.,
ASSIST. SUPERINTENDENT, X RAY DEPT., ST. THOMAS'S HOSPITAL.

THE excuse for publishing this short article is that it deals with certain facts in connexion with this disease which are apparent on radiographic examination, and which, to my knowledge, are either unknown or have never been published before. Excluding the question of injuries, one of the commonest conditions to be found in the routine examination of hospital patients is that of so-called osteo-arthritis of the spine. In fact, excluding tuberculous disease, the well-known appearances presented in this condition are continually cropping up, and it is interesting to note how often the clinical symptoms associated with other diseases can be proved to be due entirely to this pathological state. The commonest and most interesting of all is that in which the patient is sent to the X ray department suspected of renal calculus with typical symptoms of pain in either loin, sometimes very acute, and even (if the history is to be believed) of hæmaturia, although how the latter can be caused is a mystery.

An analysis of 196 cases sent to the department in 1913 and suspected of renal calculus resulted as follows:—

Calculi present	19	or	9·7	per cent.
Calculi not present	144	,,	73·4	,,
Cases not re-examined	12	,,	6·1	,,
Osteo-arthritis of spine	17	,,	8·7	,,
Nephroptosis	1	,,	0·5	,,
Calcareous deposits	2	,,	1	,,
Bone growth	1	,,	0·5	,,

From this it can be seen that the number of cases which prove to be osteo-arthritis of the spine and not calculus very nearly equalled the number of cases of renal calculus, the other conditions present totalling together only four.

The cases which were not re-examined were either those in which the patient did not attend again or in which the physician himself decided that the doubtful shadows, combined with the weak clinical history, did not substantiate the original diagnosis, and therefore were probably neither osteo-arthritis nor calculus. An examination of a very large number of cases, both on living subjects and dried specimens, has led to the conclusion that the disease is unequal in its distribution. The dorsal region is by far the commonest to be affected; then come the lumbar and sacral regions; and, lastly, the cervical regions. This distribution is important from the X ray point of view, because the dorsal region, being hidden by the heart, diaphragm, and liver shadows, is the most difficult to see; and it is extremely probable that numerous cases of even well-marked osteo-arthritis in this region are bound to be missed on the most careful examination when the disease is solely confined to this area of the body, as is frequently the case. Another important point is that the disease has to be very fairly advanced before any departure from the normal can be detected. These two points alone—namely, greater susceptibility of the dorsal region and inability to diagnose very early stages of the disease—lead to the conclusion that the condition is much more common than has been generally supposed.

Two Distinct Types, very rarely Combined.

There are radiographically two distinct types of osteo-arthritis of spine, though very rarely one sees them combined.

Type A.—The first type is very uncommon, but undoubtedly occurs; in this type there is no typical "lipping" of the articular edges of the vertebræ, but only an erosion of the fibro-cartilage between adjacent vertebræ, causing approximation of the bony segments of the spine. In four cases this had undoubtedly taken place, and was not caused by any caries (tuberculous or otherwise), and in all four cases the condition was limited to two adjacent segments in the lumbar region with the intervening fibro-cartilage. In one of these cases there was present also, lower down in the lumbar region, the typical "lipping" generally associated with this disease, and forming the second type.

Type B.—This second type can be met with in all stages, from slight "spikiness" of the articular margins to complete synostosis of the whole of the spine—forming the well-known poker-back spine. The gradual progress of the disease of this type is as follows: It may commence either unilaterally or bilaterally, and may be equally marked on both sides, or one side may be more involved than the other. Whichever way it is, the affected side or sides first shows this slight sharpening of the normally round lateral borders of the bony articular surfaces. This increases in extent, and as it increases the spikes so formed tends to turn slightly outwards and downwards in the case of the lower articular margin, and upwards and outwards in the case of the upper articular margins. Both these spiky prolongations then turn directly upwards and downwards, so that they eventually meet and fuse. Then if the disease progresses this band of opacity gradually thickens, so that eventually a solid shadow is seen surrounding the affected segments and hiding all details of the spine itself. The whole appearance (if both sides are involved) is then that of a spine over which plaster-of-Paris had been poured and then allowed to set.

This state of affairs is so unlike that presented in any other osteo-arthritic conditions seen elsewhere in the body that it seemed possible some other factors were present in the spine which allowed the disease to progress much more markedly and in a different manner than elsewhere. Accordingly, with the kind permission and assistance of Professor S. G. Shattock, to whom I am greatly indebted, a number of dried osteo-arthritic spines were examined at the Royal College of Surgeons of England and photographed and X rayed.

From the examination of these specimens two important facts were deduced, one of which has already been mentioned—namely, that even when the disease is quite well advanced the X ray plates of the dried skeleton show very little change. How much more, therefore, would be the difference in the living body when the faint shadows seen in the dried bones in the early stages would not be differentiated at all. The second fact is even more important. It can be seen conclusively from the appearance of these so-called osteo-arthritic deposits along the lateral borders of the "poker-back" spine produced, that the normal rounded outlines of the vertebræ are unaltered, and that these deposits are not bony in origin at all, but are due to calcareous masses surrounding the normal vertebræ—i.e., calcification in the lateral and sometimes central portions of the anterior common ligament of the spine. The actual bone itself is unaltered, the differentiation between the two shadows being quite plain. Consequently this condition is not that of an osteo-arthritis at all; it should rightly be termed a state of fibrositis ossificans, in order to differentiate it from the true osteo-arthritic condition seen in true bony "lipping" of the knee-joint, where actual proliferation of the bone itself takes place.

This fact suggests a possible explanation of the difference seen in the two types, A and B, of this condition. It is well known that one of the first effects of this disease is to cause atrophy of muscles and loosening of ligaments around the seat of the disease. This fact is taken advantage of in certain forms of treatment for osteo-arthritis of the knee, when by means of tuning up the muscles around the joint (by electricity, &c.), the joint surfaces of the femur and tibia, which before were pressing on the semilunar cartilages, and thus causing pressure erosion and pain, are now forced away from each other with consequent relief of the symptoms, although the actual bony proliferation of the articular edges still remains.

This state of affairs must exist also in the affected spine so that, owing to the relaxation of ligaments, pressure erosion takes place of the fibro-cartilage between the bony segments, but at the same time, or before this, calcification begins in the common ligament. If this latter condition is delayed erosion of the disc occurs, possibly followed later by calcareous deposits. If, however, as usually happens, calcification advances considerably before pressure erosion takes place, then, although the ligaments have weakened considerably, yet by reason of their solidity owing to deposition of salts the two segments of the spine are kept apart as if by buttresses, and consequently no pressure occurs on the fibro-cartilage.

MANIFESTATIONS OF HYSTERIA.[1]

BY HILDRED CARLILL, M.A., M.D. CANTAB.,
PHYSICIAN TO WESTMINSTER HOSPITAL; LECTURER ON NERVOUS
DISEASES IN THE MEDICAL SCHOOL; ASSISTANT PHYSICIAN
TO THE WEST END HOSPITAL FOR
NERVOUS DISEASES.

IT has probably seemed to some that hysteria is more important and more common of late years than in the past. For reasons which we all appreciate the patients who present hysterical manifestations are now more numerically apparent, but there is no evidence which points to a material difference in their variety. We have recently been deluged with a literature of hysteria, and on this account I must ask your indulgence for taking the subject as the text of my lecture; but the condition is of such importance and diagnostic mistakes are still so numerous that an unfailing interest in it is amply justified.

Various theories have been put forward to explain the puzzling fact that hysterical manifestations are displayed by one person and not by another; in acknowledging here the help of writers and colleagues, I should like to bear personal testimony to the excellent work of Dr. A. F. Hurst, whose conviction that hysteria consists of symptoms produced by suggestion, and therefore curable by psychotherapy has proved to be correct in what is possibly a majority of cases. In capable hands the disability has been permanently cured; but in some persons who show the manifestations of hysteria the suggesting element which results in the particular disability is amazingly difficult to discover. In the case of patients who are not cured either this definition is wrong, diagnosis is incorrect, or treatment is inadequate. The mental condition of a hysterical patient is closely connected with his special symptoms, but is not necessarily identified with them. In some patients symptoms are readily and permanently cured, leaving the individual apparently normal; in others the symptoms are perhaps cured, but the mental state fails to react to the same degree, with the result that the patient is less happy after treatment than before. The reasons for this state of affairs are thought to be fairly well known. Considerable experience is needed in order to decide correctly how much explanation of the cause of the symptom shall be given to the patient, and what proportion of the explanation shall precede or follow the cure of the symptom, but it is probable that in some cases the physician's outlook is insufficiently wide. Comparatively few possess at the same time neurological convictions adequately strong and a personality sufficiently optimistic and courageous, internally as well as externally, to carry out with constant success the treatment of hysteria. The most experienced medical man may have to deal with a nervousness lest his capacity, proved in the past, may fail him. The onlookers anticipate a cure, and if a dramatic result is not immediately forthcoming they sometimes waver audibly in opinions which a moment before seemed fixed and immovable. Many patients can be labelled hysterical at a glance. Others need diagnostic acumen. Once a case is definitely diagnosed hysterical the patient is to be regarded equally definitely as curable.

The observer, whether practitioner or friend, who first witnesses in its infancy a manifestation of hysteria is responsible if it continues, for every case can probably be strangled at the onset; but a hysterical symptom is not necessarily more difficult to cure because it has reached maturity.

A Case Illustrating Onset of Hysterical Palsy.

During a visit to a nursing home I was asked by the matron to see one of the maids who had managed to get a crotchet needle beneath the skin of her palm. "Oh, it *is* sore," she said, as I entered the room, "and I can't move any of my fingers." The needle was doing no immediate harm, but its influence was harmful, so I held its free end and ordered her to move her fingers in all directions, also her wrist, elbow, and shoulder, pain or no pain. Later the needle was removed, and she at once resumed full work. It is my custom to make a patient demonstrate the absence of hysterical sequelæ at once after every operation with a hypodermic needle, intrathecal needle, and the like. I have heard of a case of hysterical paraplegia following lumbar puncture, and I have seen severe palsy of the upper limb after vaccination, and also after a subcutaneous injection of antitoxin over the deltoid. We who sit here imagine, no doubt, that we are immune from the possibility of acquiring these manifestations, but I wonder whether we are right in so thinking. I believe that the wish is father to the thought.

---

[1] A lantern lecture delivered before the West Kent Medico-Chirurgical Society on March 11th, 1921.

Psychology of Hysteria.

I am not going to trouble you with long terms and strange words in an attempt to explain the psychology of hysteria; I believe that many are dissuaded from a study of this subject by the regrettable fact that, even in English, its language is foreign. Englishmen do not readily acquire a knowledge of strange tongues. I think it must be difficult to explain in any language the exact reasons why, for instance, one of my cases lost his hair. Seven years before I saw him he was in a fire-brigade, and during the two months which followed his burial beneath the ruins of a burning house he lost permanently every hair of his body, including those of the nares, pubes, eyebrows, and lashes. My difficulty is that I have seen no case resembling this in men who were buried during the war under nearly identical circumstances, so that we might suppose the physical and mental reaction would be similar.

I have said that we can directly prevent the consolidation of a hysterical disability without any but the most superficial examination, provided that we witness its onset and appreciate its cause. If, however, we meet the case after consolidation has occurred, at a period near to or remote from the onset, we shall examine with care, bearing in mind that a minute examination may serve to increase the patient's idea of physical illness. A sufficiently accurate examination can, as a rule, be made, under cover of conversation or the like, to exclude organic disease and, at the same time, to prevent undue interest in the mind of the patient. Above all, we must not adhere too closely to the reports of former advisers, for it is easy to have the diagnosis of hysteria suggested to our own minds to the mutual disadvantage of patient and physician. But hysteria is so very common that it should be in our thoughts in every case where there is no evidence of organic disease, or where the organic lesion has healed, or where the lesion is at best inadequate to account for the disability—given at the same time a temperature and pulse-rate which do not vary materially from the normal over a period of time. An isolated temperature of 98° F. taken in the consulting-room is apt to be misleading.

The disabilities of all of us are either physical or mental both in their origin or their continuation. The population contains more physically fit than the reverse, but it is a question whether this can be said of the entirely mentally fit. I think that many of us are mentally ill at fairly frequent intervals. No doubt it is easier to recognise this in others than in ourselves; but however this may be I feel that there is always a good chance that a patient may have no primary physical lesion.

A Mistaken Diagnosis.

The following misapplication of the practice of psychotherapy occurred in my own experience. For 18 months a young officer had limped and complained of pain in the right lower limb. For three months he had required a stick, and with this he walked about every day. He did not look ill, and no evidence of disease was detected by his physician or myself. He was able to stand and hop on the affected limb, but when he lay down he could not raise the leg against gravity. He could, however, support it in the air when it had been raised passively. He was encouraged to use the limb with considerable success, and after the examination walked back to his ward by way of an extensive garden. The same evening he collapsed suddenly and died. A sarcoma of his pelvis had reduced his acetabulum to the consistency of egg-shell, and the ischium was removed with scissors. There was extensive hæmorrhage in the thigh and retroperitoneally as high as the kidney.

In the past few months diabetes, malignant endocarditis, and cerebral tumour have been referred for treatment by psychotherapy, and I have a patient who for months wore an apparatus for foot-drop which followed the removal by frost-bite of two toes.

Varieties of Hysterical Manifestations.

There is little to be gained by a recital of the varieties of hysterical manifestations or of the precise causes of their occurrence. In the treatment of hysteria the physician deals with every department of medicine. The clinical types can be grouped broadly as follows: headache; sensory disorders of skin and mucous membranes (so-called subjective and objective), whether decrease, abolition, increase or pain; disorders of muscular contraction or control, spasms either tonic or clonic, or palsy, all of which can be voluntarily imitated, which may be manifest in abnormal gait or posture; abnormalities of speech and articulation, aphonia, stammering, and the various laryngeal and respiratory tics, including cough and hiccough; disorders of the special senses; disorders of cerebral control, such as fits, sleep-walking, insomnia, or excessive sleep; gastric and intestinal disorder, with needless vomiting, constipation, diarrhœa, flatulence, and incontinence and retention of urine. We must also remember that hysteria is seen in quite young children.

Hysterical pain is of abiding interest to us all. If a patient says he has pain we must assume that he has. It is useless to tell him that he merely imagines he has pain. Our work is to discover whether the behaviour of his pulse, temperature, sweat glands, and pupils resembles that which our experience has shown to be characteristic of proved organic mischief; and if it is not we try by persuasion to get the patient himself to modify his former opinion and statement. Pain, after all, is the reaction to a stimulus, and the reaction is variable. The duty of the physician is to weigh all the evidence and then to assess the probable value of the patient's statement.

In October, 1915, a lad sustained a comminuted fracture of the proximal phalanx of his great toe. A piece of metal had dropped across his foot. In December, 1915, the toe was amputated at the site of fracture and great pain was complained of directly consciousness was regained. This persisted. In August, 1917, I found the foot held in a varus position owing to localised pain. He was unable to do much apart from drawing his compensation payment. The toe-nails on the right foot had not once required cutting since the accident. No other evidence of disease was found, but the patient's attitude towards examination was not normal. He would not tolerate the slightest touch on the affected part unless his attention was previously distracted, and said he wanted to have his foot off; nevertheless, he got about the ward with comparative ease and slept well, the limb requiring no protection from the bed clothes. I made a note that the failure of the nails to grow was evidence of injury to the peripheral nerves, and then proceeded to cure the pain. Conversational methods were useless, so I took off my coat, grasped the toe stump, and held on. Over and over we went round and round the room, the roars of the boy arousing the hospital, but in 15 minutes he had ceased his struggles and I had won. He at once put on his ordinary boots, and in a week was back at work in the dockyard. Six months later he was still full of gratitude.

Œdema or lowered local temperature, want of expression of the part, ridges on the nails, and the like are frequently seen in hysterical conditions. They may be due to the original organic lesion of which a residue has been perpetuated by hysteria, or they may be, in the case of contracture and spasm, caused by the deformity. Thus a hysterical disability may cause an organic lesion as well as the reverse. The organic signs must not, however, be allowed to dominate the picture. A man with agony of the lower limb persisting for months after a sciatic neuro-fibroma, due to shrapnel, had been removed, and who begged for amputation, was completely cured by psychotherapy. Had the abolition of the ankle-jerk on that side, due to the initial shock to the nerve trunk, been too lovingly regarded he would still be disabled from work. Hysterical wrist- and foot-drop is often diagnosed when the condition is in reality a monoplegia, flexors as well as extensors being useless.

Among gastric cases is that of a young medical man whose epigastric hunger pain persisted in the face of a laparotomy which disclosed no disease. At his second visit to me he gave me his belt and emptied his pockets of lozenges and biscuits. A great deal of constipation is, I feel sure, due to the unnecessary prescription of bedpans; unless the risks are very great patients should be let up. In every case of persistent vomiting or regurgitation of gastric contents, witness the act. A man of 23 had for two and a half years brought up a mouthful of fluid half an hour after each meal. He then swallowed it again. Gastric lavage and bismuth meals were naturally ineffective. He mentioned tea in particular, and at his first visit, after conversation, I gave him tea. Nothing abnormal occurred and he was amazed, saying that he was better than for 12 months. "My improvement is wonderful and I cannot understand my previous treatment." A man who complained that he always belched whenever he put a pipe between his teeth was cured by opening the mouth on a gag for a time and by teaching him the needlessness of the act rather than by dieting, alkalies, and carminatives.

An instance of the overflow of needless energy, destructive and painful, yet giving a moment's pleasure withal, can be observed in a man now in my ward. He has a craze for biting through his lower lip with his incisors and for a year or more has not withdrawn his protecting finger from his mouth, either for meals or for rest or during sleep. He has shown his wisdom, however, in resisting advice to have the teeth extracted. I think it probable that many tics are merely forms of hysteria.

Hysterical affections of the bladder are fairly common and are especially tragic when unrecognised. During a night retreat in France in November, 1914, a man fell into a trench. Before, during, and after his fall he was frightened, and that night he allowed a little urine to escape in his sleep. Later on he heard someone say something about a fractured pelvis and injury to bladder, and for the next three and a half years, though well in other respects, he had passed urine every hour. His clothes were soaked and so was his mattress until he was presented with a urinal for use at night. He used it for 12 months. Treatment consisted of an explanatory statement that an injured bladder would not so behave. This was news indeed to him. Then followed a demonstration in the lavatory of perfect sphincter control.

Hysterical disorders of the special senses and hysterical fits are of vast interest. The cry which may precede the epileptic attack is not to be mistaken, but the doctor rarely witnesses the initial stage of the fit.

Malingering and Hysterical Deception.

Malingering must not be diagnosed unless the patient is found in flagrante delicto or his voluntary confession elicited, and neither of these occurrences is entirely free from the possibility of error. A man with vision of less than 6/60 was allowed to hear read out at a class the remarks of a fictitious professor that in cases of blindness which followed cerebro-spinal fever the patient could invariably see and recognise a small object when it was one among others. Having persisted in failure to see a penny on a piece of white paper, and the class having been reminded in his hearing that the man's original illness was cerebro-spinal fever, his eyes were uncovered, and he promptly recognised the details of the penny placed between two other coins. Yet I doubt if he lied consciously in the first instance.

The motives which underlie the deception of the hysteric are not always apparent. The correctness of the diagnosis is proved by the cure alone, but it does not follow that failure to cure is an indication that the diagnosis should be changed to that of malingering The following is an instance of confessed malingering. A man of 20 in 1917 came in a bath chair to see me. His right leg had been comparatively useless for nearly a year. The trouble had followed a fall from a ladder, and for many weeks he had been lying at home instead of assisting his country. He arrived at the hospital in a motor ambulance. I was prepared to consider him hysterical, even when he jumped up with alacrity on seeing me prepare the battery; he admitted, however, that he was ashamed of himself, and was told to propel the steward back to the ward in the bath chair. The following day he refused further examination, although he still limped a little, saying that his certificates about paralysis were as good as mine. The sentence of the court-martial was six months' hard labour. Possibly this served his purpose.

Preventive Treatment.

There can be little doubt that if, prior to or at the immediate onset of hysterical disabilities, a personality, professional or otherwise, was at hand the vast majority of them would be killed at the onset. The instance of the girl with the needle in the hand is a case in point. The ideal is to prevent before onset by reassurance. Nothing is so remarkable as the way in which the statements of medical men to their patients settle in their minds. For years they recall and repeat them, and when they are erroneous they may defeat the object of subsequent treatment.

Treatment of Consolidated Cases.

The essentials for this are a capacity for confident recognition of the nature of the disability, sympathy, unlimited patience, plenty of time, opportunities of seeing the patient from time to time after treatment has removed the disability, and a refusal to be put off the scent by failure. Treatment is thoroughly hard work. When in the case of a palsy I have made a decision, I photograph the patient and I tell him at the same time to arrange for the photographer to come, in say two days, to make a record of the cure. In these cases sticks and crutches are broken before treatment is started. I detain a cured case for his influence on the next, and I require a voluntary signature that the cure is complete.

(1) Methods of conversation and explanation are, no doubt, the ideal forms of treatment, but failure is fairly frequent. The intelligent coöperation of the patient is sometimes wanting. In my experience the use of faradism is of little avail except to demonstrate to the patient the integrity of the muscles or to increase by suggestion the area of normal sensation, so that by degrees it includes the area which is anæsthetic. Cases of vomiting, incontinence, fits, and so on, are specially amenable to conversational methods.

(2) I have frequently had recourse to treatment by suggestion and gross-suggestion, and with considerable success, but I am not necessarily proud of the method. Should ethical reasons dissuade us from finding with the X rays an imaginary lump pressing on the nerve in a monoplegic limb and from removing it by "deep and painful massage" under anæsthesia? Does the proved success in former cases justify us in performing an operation for a lesion which is imaginary in a case of hysterical deafness? I was criticised strongly after I performed a trephining operation[2] in a case of hysterical sleeping attacks, but my critics did not say what I should have done to the patient, who was in the habit of going to sleep during conversation. I think that those who formerly relied on hypnotism are making less and less use of it. Hysteria and a capacity to be hypnotised are not synonymous terms. Neither are suggestibility and hysteria synonymous. We are all of us suggestible, but it seems that the hysterical have a peculiar susceptibility to suggestion.

When the symptoms are cured is there anything else to cure? Sometimes there is and sometimes not. As a rule, when there is something else left it will be relieved by the accompanying conversational methods, but much depends on the presence or absence of matters connected with pension and unemployment. Cures have been stabilised by the mention of punishment in the event of relapse after demonstrated relief from disability.

---

[2] This case was described in THE LANCET, 1919, ii., 1125.

(3) Psycho-analysis is necessary to throw light on unconscious motives in other cases. To bring into the front line of consciousness repressed experiences we may make use of the most careful case-taking and inquiry with success. I confess myself to a wonder whether the ablest analyst would elicit anything of importance which I could not tell him at the outset, but until I have had some hysterical condition which has resisted cure by other methods perhaps I ought to keep silence about this. As regards conscious sexual motives and movements, homosexual and otherwise, I have been struck with the facility with which these are brought out in conversation. Drug habits may be cured when the underlying unhappiness or loneliness is made manifest and removed. The variety of the drug matters little. It is needed no longer by the patient, who is completely mentally happy. The importance of putting cause and effect in the correct sequence to masturbators is very considerable; in fact, for all disabilities, hysterical or otherwise, there is more in treatment by psychotherapy than we sometimes dream of.

TWO CASES OF

RETROPERITONEAL HÆMORRHAGE.

BY T. G. D. BONAR, M.B., B.S.LOND., M.R.C.S.,
SURGICAL ASSISTANT AND DEMONSTRATOR OF ANATOMY, GUY'S HOSPITAL.

THE two following cases may be of interest, first, because of their similarity of history and symptoms, and, secondly, on account of their difference in result and pathology.

CASE 1.—M. A., a woman aged 30, was admitted in October, 1919, complaining of abdominal pain, vomiting, and constipation of some days' standing. She was married and had had four children, all of whom were alive and well; no physical defect in them had been noticed. Her mother and father had both died from pulmonary tuberculosis, whilst she herself had suffered from anæmia and had signs of a left apicular phthisis. She gave a history of her left eye having been removed for "tuberculous trouble" some years previously, although the actual lesion we were unable to ascertain.

Her history of the present disease was as follows: Her last baby was born in December, 1918, and the day before the birth of the child she slipped and fell heavily on the pavement, but she felt no ill-effects after it. In May, 1919, she noticed dragging pains in her right loin, followed by a swelling, which moved readily when she turned from her side to her back, the swelling always falling into the most dependent position. She paid no attention to the swelling and pain, but continued with her work. Her bowels were always regular and her appetite was good. The day before her admission in October, 1919, she was suddenly seized with a violent attack of pain in her right hypochondrium, and she began to vomit incessantly a greenish-coloured fluid. She had than been constipated for the last four days.

On admission on Oct. 5th, 1919, her pulse was 98, temperature 99·2° F., and respirations 24. She looked extremely ill, had a drawn face, and was bathed in cold sweat. Her tongue was dirty, furred, and had commencing sordes. She had great pain in her right side and felt as if she wanted to vomit, although she was unable to do so. The pain travelled round from her right hypochondrium to the back of her right loin. On examination she had phthisis at her left apex and her breathing was shallow. Her abdominal wall moved well on respiration, but she was slightly rigid and tender over a small area just below her ninth and tenth ribs in her right hypochondrium. A vague swelling could be felt bimanually in the right hypochondrium and there was tenderness and swelling in her right loin. Her urine was normal; rectal and vaginal examinations revealed nothing. A turpentine enema was given, but was returned without result. After being in bed for a couple of hours she felt much easier, but five hours after admission the pain returned and was worse than before. She was now definitely tender and rigid over the whole of the upper part of her right rectus muscle. The vague tumour was still palpable, but could not be traced upwards or downwards. She was not tender under her costal arch nor for a distance of 1½ in. below it. Her pulse and temperature had both fallen, so she was given a hypodermic injection of morphine gr. 1/6th. An hour later she was much easier, and she spent a fairly comfortable night.

The next morning she again vomited large quantities of the greenish-coloured fluid. On abdominal examination she was very rigid and tender in her right hypochondrium. The previously small tender area had now increased in size, having extended as far laterally as her left rectus muscle and downwards into her right iliac fossa. By mid-day she had vomited four times, and she now was becoming distended, and peristalsis was visible on the left side of the abdomen above the level of the umbilicus.

It was decided to perform laparotomy, the diagnosis being held over. An acute cholecystitis or an appendicular abscess was suggested but the difficulty was to explain the visible peristalsis. The abdomen was opened by a right paramedian incision. On opening the peritoneal cavity the distended transverse colon forced its way out. On examining the abdominal contents the whole large gut was found to be distended, but the small intestine was not, nor was there any cause of obstruction found. The left kidney, gall-bladder, stomach, pancreas, appendix, and pelvic organs were normal. The right kidney could not be palpated definitely owing to a large retroperitoneal hæmorrhage of recent origin. The maximum amount of clot was behind the hepatic flexure of the colon, and the clot extended downwards as far as the mesentery of the appendix and to the mid-line as far as the aorta. There was no obvious cause for the hæmatoma. There was no free blood in the peritoneal cavity. The intestines were returned and the abdominal cavity sewn up.

After the operation great difficulty was experienced in getting the patient's bowels to act in spite of the frequent doses of ol. ricini, calomel, other purges, and pituitrin. After they had once begun to act no difficulty was experienced. She did very well after the operation, and at a later date she was X rayed, but no evidence of either thoracic or abdominal aneurysm was detected. She was discharged the end of October, 1919, feeling much better and looking very well.

In November, 1920—a year after her operation—she was admitted to a hospital outside London, complaining of vague pain in the right loin. On examination a large palpable right kidney was discovered. Her urine was normal and there was no history of hæmaturia, or vomiting, or polyuria. X ray examination was negative. Mr. P. Turner, surgeon to the hospital, saw her and decided that operation was necessary. She was operated on in December, 1920, and an abdominal incision was made. A tremendous amount of bleeding took place at the operation owing to the shortness of the pedicle and the slipping of a ligature. On cutting through the perirenal fat great difficulty was experienced in separating the kidney from its attachment. After freeing the kidney it was found to be swollen in its lower pole, and the outside of the kidney was coloured a deep bluish-black colour. The kidney was excised. On examining the kidney after its removal its lower pole was found to be uniformly distended and stained a black colour. On sectioning the lower pole a gelatinous black non-encapsulated mass was found to be replacing the kidney substance. A section for microscopical examination showed melanotic sarcoma. Unfortunately the woman died shortly after the operation, so that no post-mortem examination was possible to ascertain whether there were other deposits of melanotic sarcoma.

I am greatly indebted to Mr. Turner for his notes on the above case and his permission to publish it.

CASE 2.—C. B., a woman aged 44 years, was admitted to Guy's Hospital on Jan. 18th, 1903, under Dr. (now Sir) William Hale-White,[1] for pain in the back, right side, and right iliac region. Patient had been married for 20 years to a tuberculous husband and had had seven children, all of whom had died young, the cause of death in six being chest trouble and in the remaining one diphtheria. Just two years before admission patient had had an attack of severe pain in the sacral region extending to the right side. This passed off in a few days, but since then she has had numerous similar attacks at intervals varying from a week to two months. In November, 1902, patient "brought up" blood clots and fainted, but felt better afterwards.

The history of the present illness is as follows: On Jan. 10th patient had an attack of pain in her right side of such severity that she had to take to her bed. The pain subsequently extended to the sacrum and right iliac regions. Since the onset of pain there had been absolute constipation, neither flatus nor fæces being passed. Her bowels had always acted regularly until the first attack of pain, but these attacks were always associated with constipation. There had been one attack of vomiting a day or two before she was admitted.

---

[1] Med. Reps., 1903, Hale-White, No. 35.

On admission patient was thin and cachectic. The abdomen was thin-walled and distended. Surface was irregular owing to protrusions of numerous coils of distended intestine. The abdomen moved well on respiration. There was visible peristalsis. On palpation the right iliac region was tender, and there was a marked resistance of the muscles on the right side of the abdomen. Occasionally it appeared possible to feel a firm mass in the right iliac region, but a minute or two later this would be impalpable. The abdomen was tympanitic on percussion. Patient also complained of a gnawing pain in the back, which was increased by movement. Various enemata and ol. ricini were given without result. Dr. Bryant and Mr. A. L. Dunn saw patient, and concluded that the diagnosis rested between appendicitis, chronic intussusception, and malignant disease of the cæcum and ascending colon. As the general condition was good it was decided that there should be a further period of observation before operation. For two days the condition remained unchanged in spite of further enemata and purgatives.

An operation was performed by Mr. Dunn on Jan. 18th, the abdomen being opened in the right semilunar line. The whole of the intestine, large and small, was examined, but no obstruction found. It was noticed that the lymphatics of the omentum was very distended with chyle. On the day following small doses of calomel were given hourly, followed by an enema, with a result that the bowels acted several times and the patient felt better. The improvement was maintained for several days, but on the 23rd, in the evening, the patient suddenly collapsed and, in spite of restoratives, died early in the morning of the 24th. At the post-mortem examination a ruptured abdominal aortic aneurysm was found. The sac, which was as large as an orange, was situated immediately below the diaphragm. The aneurysm had ruptured at its lower right-hand corner, the aperture being the size of a florin. There was extensive erosion of the last dorsal and the first two lumbar vertebræ. There was a very large amount of retroperitoneal hæmorrhage, blood being extravasated beneath the peritoneum over the whole of the right side and down into the right side of the pelvis.

Remarks.

The points of interest of the first case were:—1. Was the patient's eye removed for tuberculous trouble or was it a growth of the eye—e.g., melanotic sarcoma? I was unable to obtain any report on this subject, and had only the patient's statement for this. 2. Was the retroperitoneal hæmorrhage due to hæmorrhage in to an early growth in the right kidney with an extravasation into the retroperitoneal tissues? The right kidney at this operation was not reasonably palpable owing to the hæmorrhage. 3. At the second operation, a year after the first, the retroperitoneal hæmorrhage had been absorbed but had left adhesions around the right kidney, making the latter difficult to remove. 4. Was the melanotic sarcoma of the kidney secondary to the eye in spite of the strong tuberculous history obtained?

In the second case it is interesting to notice the following points:—1. The strong family history of tubercle. (*Cf.* the first case mentioned.) 2. The difficulty, as in the first case, in getting the patient's bowels to act; but, once opened, no further difficulty was experienced. 3. At operation, as in the first case, no cause was found to account for the visible peristalsis. 4. Both cases gave practically the same symptoms and signs clinically, and after death each had a different pathology.

THE LATE DR. THOMAS WATT.—After practising for 35 years at Paisley, where he was held in great esteem, Dr. Watt died on May 10th, aged 59. Originally intended for the teaching profession he graduated M.A. at Glasgow University in 1882, but afterwards took up the study of medicine, and in 1886 obtained the degrees of M.B., C.M., immediately entering upon general practice. In 1899, when there was a severe epidemic of enteric fever at Paisley, Dr. Watt took charge of the Infectious Diseases Hospital. Later he visited Germany, Denmark, and Holland in order to study milk-supply in connexion with tuberculosis, and on his return to Scotland was associated in a campaign to educate the public on the relation of milk in the prevention of consumption. At the time of his death he was senior visiting physician to Paisley Infirmary. He was also medical representative on the board of directors of the Royal Victoria Infirmary and medical officer to the post-office there. During the war he was actively associated with the work of the Red Cross.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF TROPICAL DISEASES AND PARASITOLOGY.

AT a meeting of this section of the Royal Society of Medicine on May 2nd, presided over by Surgeon Vice-Admiral Sir ROBERT HILL, a paper was read by Sir LEONARD ROGERS entitled—

The Mortality and Prognosis of Cholera Treated by the Author's Hypertonic Saline Method, based on 2000 Cases.

The hypertonic solution used was composed of 120 gr. of sodium chloride, 6 gr. of potassium chloride, and 4 gr. of calcium chloride to the pint of sterile water. It was administered intravenously, under strictest antiseptic precautions, at a temperature usually of 98–99° F. in amounts of one to two quarts according to the severity of the case, a period of at least 15 minutes being taken for the injection of one quart of fluid. That method of treatment introduced in 1908 to 1909 had proved a considerable advance on the use of rectal, subcutaneous, and intravenous injections of the normal isotonic salines formerly employed, and particularly so in association with the more recent administration of alkali and permanganate. A series of tables and diagrams providing a graphic record of the results of treatment by that means in the cholera wards of the Medical College Hospital at Calcutta, and of the various observations on patients suffering from the disease, together with the case-rate and mortality figures, were thrown on the screen and explained during the course of the lecture. An account was given of observations on the blood changes in cholera, including the blood pressure, specific gravity, the percentage of blood corpuscles obtained by the hæmocrite, and of the beneficial effect on the blood by means of hypertonic saline injections, which had materially improved the prognosis of cases. Indications for its use were failing pulse, blood pressure below 70 mm., and specific gravity over 1060.

Examples of the degrees of blood concentration and loss of fluid.—Taking the averages in seven fatal cases it was shown that the normal percentage ratio of the volume of blood corpuscles to serum being about 45 to 55, the percentage of corpuscles was increased to 71 and the percentage of serum reduced to 29, with a loss of fluid from the blood amounting to 64 per cent. In 12 cases recovering after transfusion the average percentage ratio of corpuscles to serum was 63 to 37 and the loss of fluid from the blood 52 per cent.; in five mild cases not transfused the average volume of corpuscles was 56 to 44 per cent. of serum and the loss of fluid 35 per cent.

Seasonal incidence.—Both before and after the introduction of the new treatment in 1908 the case-rates and death-rates tabulated month by month showed the highest mortality in the beginning of the year, and the tendency of the death-rate to fall steadily through the hot weather, attaining a minimum in the rainy season coincident with the greatest number of cases. The seasonal incidence was therefore of considerable importance, the case-rate being highest and the death-rate lowest during the rainy season.

Race and sex-incidence.—Statistics derived from the Calcutta Medical College Hospital, 1895 to 1905, had revealed no special susceptibility attaching to any one race. The Chinese, however, had proved much more resistant to the disease than Hindus. Males were attacked in greater numbers than females, probably owing to their more frequent exposure to infection. Although so pronounced a fall in the death-rate had been achieved by the new treatment, the relation of race and sex-incidence to mortality still showed no marked variation of either factor. (Table I.)

Among females exception occurred in the case of pregnancy, which considerably lessened the prospect of recovery from an attack of cholera, and therefore justified resort to premature delivery. The effect of the new treatment on the death-rate at various ages was remarkable. Under the old method of treatment in 1895 to 1905 the mortality among patients under 10 was 52·8 per cent., increasing as age advanced, to reach 73·7 per cent. among those over 50 years. With the use of hypertonic salines the reduction which had occurred in the death-rate of cases between the ages of 5 and 50 years was a very important feature, and for patients under the age of 10 it had fallen to 16·4 per cent. The influence of the duration of the disease previous to admission and treatment on the number of fatalities and cause of death was demonstrated by the striking fact that, if the attack had lasted 12 hours, collapse was the cause of death in 67·4 per cent. of fatal cases; and if admission had been delayed for 24 hours from the onset, death from uræmia occurred in 54·8 per cent.

TABLE I.

Race.	Percentage mortality.		Sex.	Percentage mortality.	
	1895–1905.	Under new treatment.		1895–1905.	Under new treatment.
Hindus	61·6	21·6	Males... ...	60·3	20·7
Mahomedans...	57·3	20·4	Females ...	60·3	19·9
Europeans ...	56·5	18·8			

The relationship of the specific gravity of the blood to the case mortality showed that the closer the blood approximated to the normal the lower was the death-rate—e.g., with a specific gravity of 1055 12·7 per cent. of cases proved fatal, but with a rise in specific gravity, 1067 to 1071, the death-rate was nearly doubled. It became evident that with specific gravity above normal more frequent saline transfusion was necessary, increasing in quantity from 1 litre if the specific gravity was 1062, to 2 litres if specific gravity rose to 1066. Study of the relation of blood pressure to cholera death-rate showed that with falling blood pressure the mortality increased, but the tendency to fall was counteracted by the treatment. In cases with blood pressure of 90 mm. or over the death-rate was 15·2 per cent., but rose to as high as 84·7 per cent. when the blood pressure fell below 70 mm. (Instances from Table I.). The effect of fall in blood pressure on the condition of collapse was also described, and examples showed that with a blood pressure of 90 mm. or over collapse occurred in 9·3 per cent. of cases, and in as many as 93·7 per cent. when the blood pressure fell to 70 mm. or under. It had been found essential to apply the treatment as soon as the blood pressure fell.

Low alkalinity of the blood in cholera.—Dr. Sellards, working in the Philippines, found that large doses of alkali could be given in cholera without increasing the alkalinity of the blood, and he had used injections of 2 per cent. sodium bicarbonate with success in overcoming anuria and relieving collapse. Colonel J. W. D. Megaw, who had seen Sellards' work, in 1911 gave injections of alkali with good effect in cases of choleraic uræmia. His own observations showed that reduction in the blood alkalinity of cholera patients was attended by an increase in the death-rate—e.g., with an alkalinity of N/45 the mortality was 12·5 per cent., if reduced to N/80–N/100 the death-rate rose to 27·3, and a still further fall in alkalinity below N/100 produced a mortality of 60 per cent. It was therefore apparent that a close relationship existed between falling blood pressure, a high specific gravity, low alkalinity of the blood and a high death-rate in cholera, and it was important that routine administration of alkalis should be carried out from the onset of the attack to avert fatal uræmia. The tabulated results showed that without alkali treatment the death-rate was 25·6 per cent., and in 11·1 per cent. the direct cause of death was uræmia, but under alkali treatment the mortality fell to 19·7 and uræmia provided only 3·95 per cent. of the deaths. Full details of four cases were quoted, showing the beneficial action of alkalis in increasing the flow of urine, raising the blood pressure, and reducing the high specific gravity of the blood, with the result that three out of the four cases recovered. Further particulars were given illustrating the relation of blood pressure and specific gravity of blood to the amount of urine secreted, and emphasis was again laid on the necessity for saline and alkali treatment in order to maintain the flow of urine. For the fall in urinary output coinciding with a low blood pressure of 75 to 80 mm. and a high specific gravity of the blood accentuated the dangerous association of blood concentration and arrested renal function, the combined result of the great drain on the tissue fluids caused by the frequent and excessive evacuation of the bowels.

The influence of the temperature on the death-rate in cholera was shown by records of rectal temperature and the corresponding case-mortality (Table II.).

TABLE II.

Temp. over.	Deaths per cent.	Temp. over.	Deaths per cent.
103° F.	5·2	95° to 96°	33·6
101°	9·1	95° and under	50·0

Owing to failing circulation and consequent increased heat loss from the body surface, it occasionally happened that axillary temperature readings were lower than the rectal.

Considerable interest attached to Table III., showing the relationship of the mortality rate to the number of hypertonic saline injections during the years 1912 to 1919.

TABLE III.

Year.	Death-rate per cent. of cholera cases.		Number of saline injections.			
			0–1	2–3	3–10	
1913 ...	24·5	Given in—	30·0	42·0	28·0	Per cent. of cases.
1915 ...	17·2		15·8	26·3	57·8	
1917 ...	14·6		20·0	16·7	63·3	
1919 ...	22·6		47·2	24·6	28·2	

Previous to 1918 the number of cases treated in hospital by the hypertonic saline method was about 200 in each year, but in 1918 this figure rose to over 300, and in 1919 to over 400. The table showed that for any given year the higher the percentage of cases receiving the larger number of injections the lower was the death-rate, particularly was this evident in the years 1915 and 1917. During 1918 and 1919 the number of cases requiring the treatment was so great that it was impossible in a large proportion of cases to administer more than one or two injections, consequently the case-mortality rose for those years.

The method of treatment by salines which had been employed during the last 25 years could be divided into periods as shown in Table IV.

TABLE IV.

Year.	Treatment.	Results in percentages.	
		Deaths.	Recoveries.
1895–1905.	Rectal and subcutaneous salines.	59·0	41·0
1906.	Normal salines intravenously.	52·0	48·0
1907.	Rectal and subcutaneous salines.	59·5	40·5
1908–1909.	Hypertonic intravenous salines.	32·6	67·4
1909–1914.	Hypertonics plus permanganates.	25·9	74·1

In subsequent years, by the addition of alkalis to the improved treatment already developed by the use of hypertonic saline and permanganates, there had resulted a still further reduction in the death-rate to 19·1 per cent. for 1915–1917.

Discussion.

Surgeon-Rear-Admiral P. W. BASSETT-SMITH said that Sir Leonard Rogers's work on cholera supplied the best example he knew of the value of the application of scientific methods of deduction to the securing of successful treatment. The large number of statistics given had rendered possible the drawing of conclusions from the results, for it was important to have figures over a range of years. He himself had had no personal experience of the use of hypertonic salines, but he recalled in his early days in China the success attending the use of isotonic saline injections by Dr. Jameson in Shanghai, which established that means as the correct line of treatment in cholera, in order to replace the loss of tissue fluids, to encourage the secretion of urine, and to counteract uræmia.

Dr. P. H. MANSON-BAHR stated that opportunities of treating cholera in Egypt during the war had been few owing to the small number of cases which had occurred. He regarded the pathology of collapse as likely to be much the same in bacillary dysentery as in cholera, and to call for the same treatment. Although Sir Leonard Rogers's apparatus and outfit for dealing with cholera had been available, official sanction for its application in cases of dysentery was refused because the patients were not suffering from cholera!

Dr. W. BROUGHTON-ALCOCK had had opportunity of applying the hypertonic saline treatment with benefit in cases of bacillary dysentery, following the line of observation of the specific gravity of the blood. He had found the method of considerable help in cases of extreme collapse due to Shiga dysentery. He asked Sir Leonard Rogers how it was possible to diagnose mild cases of cholera quickly, for rice-water stools did not occur as often as he would have expected in mild cholera.

Sir LEONARD ROGERS, in his reply, referred to the successful use of isotonic or normal salines in China, and the fact that the Chinese were more resistant and responded better to the injections than did the Hindus. Failures in the past attending the use of salines by Dr. A. J. Wall in India had been due to the fact that he had employed not isotonic but hypotonic salines of 0·6 per cent. chlorides or 0·2 per cent. chlorides and 0·4 per cent. bicarbonate, instead of the 0·9 or 0·85 per cent. chloride of the normal isotonic saline. Bacillary dysentery responded well to hypertonic saline injections, together with rectal wash of permanganate. Saline treatment, especially if the solution was above normal, was of great value also in blackwater fever. For the diagnosis of mild cases he said that Colonel Greig relied on cultures grown on Dieudonné's media and then testing for agglutination with various strains of anticholera serum. Cholera tended to appear in cycles, one year of high being followed by another of low prevalence. The larger the number of cases the lower was the mortality, and the milder cases occurred towards the end of an epidemic.

The Ankylostomiasis Campaign in Egypt, 1913–1915.

A paper on this subject by Dr. A. F. MACCALLAN was read, in the absence of the author, by Dr. W. T. PROUT, honorary secretary of the section. As the result of reports on the prevalence of ankylostomiasis in middle Egypt by Sir David Semple and Dr. Graham, Lord Kitchener in 1913 instructed Dr. MacCallan to organise a campaign to investigate and deal with the disease, which was widespread in country districts and native villages. The sum of £E.12,000 was available for the campaign and this was directed to the erection of tent hospitals of 50 beds in the various villages, and travelling dispensaries to reach the more remote parts. Efforts were also made to improve the sanitary conditions, or rather to introduce sanitation in places where it did not exist, for the proper disposal of excreta, and to erect brick latrines. Under his direction a survey of the provinces of Shargui and Assiut was made by the late Dr. Stimner and Dr. Kennedy. The two provinces were divided into several areas, each of which was visited in turn by the travelling hospitals and mobile laboratories. Under the supervision of the two medical officers systematic examinations of the blood and stools of large numbers of the male natives were carried out by trained assistants. The stools in each case were submitted to washing and centrifugation, and at least ten minutes was devoted to the microscopical examination of the deposit for the parasitic ova before a negative report was returned. As the result of these investigations it was estimated that in Shargui province, with a population of 620,000, the incidence of ankylostomiasis infection among males amounted to 56 per cent., and in Assiut province, with a population of some 450,000, the incidence was about 46 per cent. It was only possible to examine about 1 per cent. of the population, and owing to the difficulty of obtaining specimens from female natives the examinations were perforce restricted to males. Through the agency of the travelling hospitals and dispensaries treatment by thymol was carried out with considerable success, the results amounting to over 70 per cent. of cures among patients treated. Valuable information was also obtained in the course of the surveys as to pellagra and bilharzia. Owing to the interference of the war the special campaign against ankylostome infection was necessarily suspended in 1915 and much then remained to be done to cope with the problem in the affected areas.

Based on what had already been accomplished, the need for the following preventive measures was advocated by Dr. MacCallan: (1) Recognition and obliteration of the habitat of the ankylostome larvæ; (2) introduction of proper sanitary measures in the villages and provision of a suitable pail system for the disposal of excreta; (3) erection of shelters in the villages for the treatment of infected natives; (4) treatment on scientific lines of cases of anæmia in the country districts; (5) research investigations as to the nature and action of the toxins of *Ankylostoma duodenale*.

Discussion.

Sir ROBERT HILL much regretted that Dr. MacCallan had been prevented from attending the meeting to deliver his paper.

Dr. J. B. CHRISTOPHERSON stated that the problem of ankylostomiasis in Egypt opened up a large field for investigation and treatment. From his own experience there he emphasised the need for peripatetic hospitals among the villages to deal with the three principal plagues of Egypt—namely, ankylostomiasis, bilharziasis, and *Tænia nana* infection—which were diseases of the agricultural rather than the urban districts. The Egyptian native was very amenable to treatment and ready to avail himself of it when brought to him by the travelling hospital, but he was unwilling to go out of his way to obtain necessary relief.

SECTION OF LARYNGOLOGY.

EXHIBITION OF CASES AND SPECIMENS.

A MEETING of this section of the Royal Society of Medicine was held on May 6th, Dr. W. JOBSON HORNE presiding.

Abduction Paralysis in Exophthalmic Goitre.

Mr. T. B. LAYTON showed a middle-aged woman, the subject of Bilateral Abduction Paralysis associated with Exophthalmic Goitre. For the goitre she had been under observation and treatment since 1895. She had diphtheria in 1887, and she still continued to have attacks of sore-throat.—Sir JAMES DUNDAS-GRANT suggested that the symptoms may have been due to pressure exerted by the enlarged thyroid gland on the sympathetic nerve.—The PRESIDENT said that surgical interference was usually blamed for such paralyses when there had been an operation for the condition, but in this case there had been no surgery. He agreed with Mr. E. D. DAVIS and Sir WILLIAM MILLIGAN in the rarity of such paralysis in exophthalmic goitre.

Suppurative Sequelæ of Scarlet Fever.

Mr. LAYTON and Mr. J. F. O'MALLEY showed cases of this kind. Mr. Layton's case was one of frontal sinusitis in a child, aged 12, which came on in the course of scarlet fever. There was a subperiosteal abscess. The bone beneath was healthy, but a track led down to the front of the inner wall of the orbit, where the pus had escaped from the ethmoid cells through the lacrymal bone. The frontal sinus was full. An ugly scar resulted. Mr. O'Malley's case was one of bilateral subperiosteal suppuration of the orbit, due to ethmoidal suppuration, which had supervened during the scarlet fever. His operation of drainage of the ethmoidal region caused the swelling to subside, but did not quite eradicate the ethmoidal disease.—Sir WILLIAM MILLIGAN related a case which had had a number of operations done on the continent unsuccessfully, leaving gross disfigurement. After his own successful operation he greatly reduced the deformity by means of a pure gold plate, which was found by X rays to be still in situ more than 12 years subsequently.

Tumour of Pharynx.

Mr. W. H. KELSON showed a young man with a Tumour in the Pharynx. He had been operated on for enlarged tonsils and adenoids, and had had treatment for antral, ethmoidal, sphenoidal, and frontal suppuration.—Other cases were also shown.

Reviews and Notices of Books.

A PHYSICAL INTERPRETATION OF SHOCK, EXHAUSTION, AND RESTORATION.

By GEORGE W. CRILE, M.D. Edited by AMY F. ROWLAND, B.S. London: Henry Frowde and Hodder and Stoughton. (Oxford Medical Publications.) 1921. Pp. 232. 25*s*.

IN this work Dr. Crile has collected the evidence concerning shock accumulated during the last few years by himself and his fellow workers. He attempts to show that the degree of shock is proportional to the extent and duration of injury and to the richness of the nerve-supply in the injured part; that regional nerve-blocking or cocainisation of the bulb and spinal cord is effective in preventing its onset; that "trauma alone or sufficient strychnine alone causes exhaustion of the vaso-motor centre" after producing preliminary stimulation; and that this stimulation does not occur in the unshocked animal if the bulb and cord are anæsthetised with cocaine. Dr. Crile puts forward the evidence of changes in the brain cells, through a hyperchromatic stage to final disintegration, which result from trauma, but which, he says, do not occur "if the trauma is limited to territories disconnected from the brain by section of the spinal cord or by local anæsthesia." He again places on record his observations with Dr. Dolley on "Anæmia and Resuscitation," and notes the important fact that the brain-cell changes are "in certain respects identical with those in shock." The minute morbid anatomy of the brain, liver, and adrenals in experimental insomnia is described, together with the restorative effects of sleep, morphia, and nitrous oxide anæsthesia. According to Dr. Crile, similar changes occur in these organs after severe exertion, emotion, infection, hæmorrhage, starvation, asphyxia, chloroform, and ether anæsthesia, electrical stimulation, the administration of adrenalin, excessive thyroid feeding, and finally after the excision of the adrenals, thyroid, or liver. Changes in H-concentration and reserve alkalinity in these conditions are briefly mentioned, and, lastly, the results of certain observations of the electric conductivity of the brain, liver, and other organs are given.

This mass of evidence requires extremely careful and critical study, and it is unfortunate that the form in which it is put forward does not lend itself to such inquiry. For instance, Fig. 57, on p. 68, is supposed to demonstrate increase in the output of adrenalin due to the presence of foreign protein, whereas the only inference that can legitimately be drawn from the data presented is that the blood of the pregnant cat sometimes contains a demonstrable amount of adrenalin. Again, Fig. 58, on p. 69, is a tracing intended to show the effect of anaphylaxis in causing increased output of adrenalin and the influence of morphia in preventing such change. The legend refers to "the injection into a morphinised animal of beef serum, which in the normal animal would have caused a strong anaphylactic reaction." There is no reference to any previous sensitising injection, and, on the face of it, it appears that the author regards the effect of a single injection of foreign protein as equivalent to an anaphylactic reaction. Some of Dr. Crile's passing comments are also disquieting. On p. 70, for example, he says:—

> "In cases of suboxidation and asphyxia the outstanding phenomena are diminished voluntary muscular activity and diminished mental activity. In contrast, however, there is increased respiratory activity. If our explanation of these phenomena is that they are due only to the want of oxygen, then why is not the activity of the respiratory system diminished for the same reason?"

Dr. Crile seems for the moment to have forgotten the important part played by increased partial pressure of CO_2, and by changes in H-concentration, in the regulation of the respiratory centre, also that anoxæmia is not the sole factor in asphyxia. Finally, we cannot admit the validity, even as collateral evidence, of the observations made on the electrical conductivity of presumably dead tissues, in the investigation of the functional changes of living cells.

In his discussion of the ætiology of shock and exhaustion the author describes various theories put forward. He ignores the work of the Special Investigation Committee on Shock and Allied Conditions, set up by the Medical Research Council,[1] and dismisses in a few words the evidence that in shock the effective blood volume is diminished by the collection of blood in widely dilated capillaries, which are not, as far as we know, directly under the control of the central nervous system. The brain-cell changes which he describes may equally well result secondarily from anæmia. In his attempt to demonstrate the preponderating importance of a primary assault on the central nervous system in shock, Dr. Crile brings forward a great deal of evidence, some of which is highly dubious—for example, the work of Alexander and Cserna[2] on the oxygen consumption of the brain. He regards the anæsthetic action of nitrous oxide as being wholly dependent on its interference with the use of oxygen by the brain cells, and has apparently overlooked G. T. Kemp's[3] work in this regard. He refers, on p. 119, to the fact that "the brain cells have no basal metabolism except that of energy transformation, associated with work," but on the previous page he states, on the authority of Mathews, that "sugar is burned in the brain." Whether this occurs only during consciousness he does not say. It is, however, in his presentation of an "electro-chemical" hypothesis as to the method of exhaustion that Dr. Crile departs furthest from the fundamental data of physiology. His assumption that the brain cells are electric batteries and the nervous impulse neither more nor less than an electric current is untenable and can only lead to confusion.

The book contains so much interesting material that it is a matter of regret that Dr. Crile did not give more experimental details in order to permit of intelligent comment and criticism, instead of complicating this difficult subject by the presentation of hypotheses impossible to verify. The volume is excellently printed and the illustrations are satisfactory, though some of the blood-pressure tracings would be easier to analyse if the writing upon them were not too small to be decipherable without the aid of a hand-lens. A useful bibliography is appended.

CATALYSIS AND ITS INDUSTRIAL APPLICATIONS.

By E. JOBLING, M.C., A.R.C.Sc., B.Sc. London: J. and A. Churchill. 1920. Pp. 144. 7*s*. 6*d*.

THIS volume is the second edition of one of a series of text-books on Chemical Research and Engineering, edited by Mr. W. P. Dreaper. Berzelius, as long ago as 1835, defined as "catalytic" the phenomenon that many chemical reactions which proceed slowly may be accelerated by the introduction of some foreign material. Since that time great and important advances have been made in chemical industry by means of catalytic agencies. The literature on the subject is voluminous, and Mr. Jobling has rendered a service to chemists in preparing this volume, for it will appeal both to the student and to those who desire a readable account of the technical applications of catalysis. The chapters on sulphuric acid manufacture, industrial chlorine, and fixation of atmospheric nitrogen are of particular interest, as is also the one dealing with the most recent offspring of catalysis—viz., the hydrogenation of fats.

[2] Alexander and Cserna: Bioch. Zs., 53, 100–115.

[3] G. T. Kemp: Brit. Med. Jour., 1897, ii., p. 1480.

The style of writing is lucid. A useful feature is a list of references, including patents and bibliography, at the end of each chapter.

DISEASES OF THE STOMACH.

Diagnostik und Therapie der Magenkrankheiten. Seventh edition. Von Professor Dr. I. BOAS. Leipsic: G. Thieme. 1920. Pp. 671. M.138.5.

To any who are not familiar with Professor Boas's name as a European authority upon diseases of the alimentary canal the fact that this volume is the seventh edition of a work which first appeared 30 years ago is evidence enough of the lifelong interest and experience of the author in that province of medicine. Much progress has been made in 30 years; indeed, the student of human nutrition who has followed his subject over that period has known intellectual adventures of rare quality. He has seen the principle of the conservation of energy applied to man; has watched chemical, physical, and surgical methods transform the study of abdominal disease from a morass of inaccurate generalities to a cultured field of medical science; he has seen, most unexpected of all, the gigantic experiment of the rationing of nations; and, lastly, has looked upon the spectacle of the under-nutrition of half a continent. Most changes have their drawbacks, even changes for the better; and the disadvantage of the application of chemistry, physics, and surgery to the diagnosis and treatment of disease is that the doctor is sometimes apt to allow the test, or the photograph, or the operation to take the place, in whole or in part, of that careful study of the history, symptoms, and signs which was, is, and must be the basis of his work. Professor Boas's book will counteract any such tendency. It is full of clear common sense as well as accurate knowledge of clinical medicine and laboratory work.

The first part treats of general methods of investigation. A good account is given of the tender points which the author has described near the spine in diseases of the stomach and gall-bladder. Tenderness on deep pressure to the left of the spine between the tenth dorsal and first lumbar vertebræ, usually opposite the twelfth dorsal, suggests gastric ulcer. With pyloric and duodenal ulcers there may be a tender spot to the right of the spine. With gall-stones the tender point is two or three fingers' breadth to the right of the twelfth dorsal vertebra and may be as far out as the posterior axillary line; it may persist for weeks or months after an attack of biliary colic. The difficulty of not knowing how hard to press is got over by the use of the algesimeter, which records the pressure against a spring. A normal man bears 5 to 10 kilogrammes with this little instrument, whereas tenderness is elicited at the pressure point in a case of gastric ulcer with 3 kilos. The description of chemical methods is excellent, but that of X rays is inadequate. It is clear that, though the author makes use of X rays and shows some plates, he has not had the advantage of close coöperation with a good radiologist. For example, 2½ pages are devoted to methods of blowing up the stomach with air or other gas, 15 pages to dietetic methods of determining the motor power, and only 5 to the general description of the use of X rays; although the barium meal offers the quickest, safest, and most informing way of finding out the shape and motor power of the stomach. In the account of the various forms of gastroscope, coloured pictures are given of the appearance of the gastric mucous membrane. The author does not think that the last has been heard of this instrument, although radiology has put it in the background for the time. He agrees with most workers that the limits of gastric acidity in normal people are fairly wide, 0·15 per cent. to 0·2 per cent., also that a high figure may be obtained in those who have no symptoms, especially in heavy smokers and people who consume much meat and condiments.

The second part of the book is devoted to general methods of treatment. Of these diet occupies much space, the teaching being substantially that of the author's Special Dietetics, recently reviewed in these columns. Of other methods of treatment described baths, massage, electricity, poultices, stomach washing, and medicines are all dealt with systematically.

The last part, dealing with special diseases, contains much interesting matter. The importance of diagnosing achylia or subacidity, the symptoms of which are sometimes misleading, is referred to. 16 per cent. of 3147 chronic dyspeptics were found by Kelling to be suffering from this disorder. Such figures, however, must not receive too much attention, for an up-to-date X ray examination or an exploration would probably have shown that some of these were not the subjects of simple achylia. In writing of hyperchlorhydria, the view is put forward that some cases with symptoms but without ulceration are suffering from small erosions. The author notes that treatment commonly leads to disappearance of symptoms, although the hyperacidity as shown by test meals is unaffected. This is in complete accord with the best experience; we should look upon the presence of hyperchlorhydria as a valuable guide to treatment rather than as a condition which can be altered in a short time. Professor Boas would exclude salt from the diet, but regards the measure as of temporary benefit only. Sodium bicarbonate has been found to lessen secretion when given in small doses on an empty stomach, though, when given with food, secretion is increased, probably because of the production of sodium chloride and carbon dioxide. He is, on these grounds, against the taking of bicarbonate at the height of secretion, saying, however, that it may be useful during the healing of an ulcer. Alkali should, as a rule, be taken in small doses before food, though he does not think that it can systematically diminish the secretion of HCl. The form recommended is a mixture of bicarbonate of soda and magnesia, with reduction of salt in the food. He is doubtful about atropin, but recommends Merck's magnesium perhydrol in ½-g. doses, which in the acid stomach forms magnesium chloride and peroxide of hydrogen, the latter decomposing to water and oxygen. In gastric ulcer a distinction is drawn between the treatment of a simple ulcer and of the general liability to ulceration, the "ulcer disease." The treatment of the latter must be over a long period, and is needed whether the simple ulcer is operated upon or not. In about half the cases medical treatment does not lead to a permanent cure. It should always be tried first, except in patients who cannot afford the necessary time or money, or who cannot get suitable diet. Gastro-enterostomy is recommended for pyloric ulcer, and resection, if the technical difficulties are not too great, for ulcer of the body of the stomach. The author says occult blood is commonly present after gastro-enterostomy.

The X ray diagnosis of cancer of the stomach is inadequately described; for example, the characteristic rapid emptying with a gaping pylorus in cancer of the body is not mentioned. In the chapter on gastrocoloptosis the relation of this condition to a general asthenia is given prominence, and wise and sound rules are laid down for treatment. The author does not recommend operation by stitching up the stomach or the bowel—first, because in nearly all cases suitable treatment by appropriate feeding, rest, massage, &c., leads to relief; and, secondly, because dropping of these organs is, as above mentioned, frequently part of a general condition which operation does not benefit. Even after stitching is done the same general treatment has to be carried out for the same length of time as if the operation had not been done, if a good result is to be secured. The diagnosis and treatment of numerous forms of gastric neurosis are described carefully, a useful classification being adopted into neuroses with one symptom—such as anorexia, nausea, pain, rumination, excessive peristalsis—and neuroses with more than one symptom.

This book is written from a broad and sensible standpoint and contains an unusual amount of close observation and wise advice. The author refers to several French authors, but appears to be almost unacquainted with contemporary British and American work, a neglect which may be due in whole or part to the inaccessibility of foreign books.

Gynæcological and Obstetrical Tuberculosis.

Gynæcological and Obstetrical Monographs. By Charles C. Norris, M.D., Associate in Gynæcology, University of Pennsylvania Medical School, &c. London and New York: D. Appleton and Co. 1921. Pp. 356. 21*s*.

Dr. Norris believes that tuberculosis of the female genital tract and peritoneum is of frequent occurrence, but that it is usually secondary to tuberculosis elsewhere. After a short historical sketch he considers the diagnosis by laboratory methods, and concludes that histological examination is usually sufficient, but that in doubtful cases animal inoculation should be carried out. A chapter is then devoted to the pathology of the chief forms of tuberculosis in the various parts of the genital tract, followed by a very interesting survey of congenital and placental tuberculosis. The conclusion is come to that these are very rare conditions, and that, for a congenital hæmogenic infection to occur, a maternal bacillæmia and a permeability of the placenta must be present. The disease is believed to arise in four ways: (1) by direct infection through the blood stream, (2) by direct infection from without, (3) by extension of a near-by focus, or (4) by a lymphatic infection. Tuberculosis affecting the various parts of the genital tract is considered in detail, and a large number of useful case-histories from the literature and from Dr. Norris's own experience are given. There is an instructive chapter on the important subject of pregnancy and tuberculosis. The writer maintains that in the presence of an extensive lesion, even in the quiescent stage prior to the fifth month of pregnancy, the uterus should be emptied. After the fifth month, however, little can be accomplished other than general hygienic and dietary treatment. As a general rule it is best to hasten the labour by applying forceps when the cervix is fully dilated.

The final chapters deal with the menstrual disturbances in pulmonary tuberculosis, the dangers of operations in this disease, tuberculous disease of the breast, and tuberculosis of the peritoneum. An analysis of 2356 cases of the latter condition treated surgically show some 31 per cent. permanently cured, 30 per cent. definitely improved, and 36 per cent. with recurrence, the development of tubercle elsewhere, or death from intercurrent disease. The book is a valuable contribution to the literature of this important subject.

Margarine.

Monographs of Industrial Chemistry. By William Clayton. London: Longmans, Green, and Co. 1920. Pp. 187. 14*s*.

In this volume the author has given a clear account of the modern processes involved in the manufacture of margarine. The methods of analysing the finished product and its constituents and the chemical properties of these are described, and butter, renovated butter, and lard compounds are also dealt with. A chapter on nutritional chemistry will doubtless be perused with considerable interest by our readers, as in it the results the investigations on vitamins so far as they affect ter and its substitutes are discussed. Butter pre-inently is the source of the essential "fat-soluble vitamin. The oleomargarines, containing 50 per cent. of beef fats, are good substitutes for butter, and their value in this respect is improved by admixture with butter itself to the legal limit of 10 per cent. Most oleomargarines contain lard, which is known to be devoid of "fat-soluble A," and it follows, therefore, that the animal fat portion of an oleomargarine should not contain lard. Vegetable oils and fats, and hydrogenated oils are lacking in this vitamin, so that the "vegetable" or "nuts and milk" margarines are not substitutes for butter from the true dietary point of view.

The author has rendered a service to technology in preparing this volume. Margarine has come to stay and its cheapness and ease of manufacture render it a formidable rival to butter. The product is capable of considerable improvement, particularly in the matter of texture and flavour, but in view of the great amount of technical investigation, which, to judge from this volume, is being directed to these points, there is every hope that margarine in the near future will be indistinguishable by the palate from butter. Mr. Wilson has included a number of good illustrations and a useful bibliography.

The Things which are Seen.

A Revaluation of the Visual Arts. By A. Trystan Edwards, M.A. London; Philip Allan and Co. 1921. Pp. 354. 18*s*.

This is a very interesting book, and one which gives occasion for much thinking, even though we may not always agree with the author's ideas. He deals, as is clear from the title, only with the *visual* arts, music and literature being excluded. He arranges the visual arts in the following order: first, the cultivation of human beauty; second, the art of manners; third, the art of dress; fourth, architecture; and fifth and sixth, the minor arts of painting and sculpture. This order, though it may give offence, he admits, "to many who are accustomed to arrogate to themselves the title of artists, can be shown to be in complete accord with the judgment of mankind, with that mature judgment which best finds its reflection in the opinions of the average man." The reader will ask himself who is the average man intended in the quotation, and Mr. Edwards does not tell us definitely. But he makes obvious who he is not: he is not the representative of public opinion. We endorse this view that the real preferences of the vast majority of people are shown, not by what they say or are taught to say, but by what they do; whence it follows that, by examining the deeds which men perform and the conventions established among them, we can obtain a more accurate idea of our fellow-men than can be obtained from any attention to the expressions of sentiment heard on all sides. Mr. Edwards's thesis is that the value of the arts is in direct relation to their benefit to society, and he places the cultivation of human beauty in the first place, because a high general standard of beauty will not be achieved unless the social virtues are practised.

In a general review in the first portion of the book Mr. Edwards refers to his omission of literature and music, and with regard to the latter art makes a statement with which we cannot agree: "Rhythm and melody can never give complete satisfaction to the average man unless they are brought into direct relation with human life by being associated with a song or a dance, a theatrical or operatic display, or some form of ceremonial." We own that it is difficult for any one of us to say what may completely satisfy his neighbour, but we have seen a packed audience standing in the area of Queen's Hall on a hot August night listening with delight to Bach's concerto for two pianos in C major, and demanding the repetition of the brilliant fugue with which the work concludes; the performance did not come under any of the heads mentioned by Mr. Edwards. Such artistic triumph can have no relation to successful effort; and as the art of music was definitely left out of the scope of the work, it might have been better not to drag it in with any comment.

The second part of the book deals with form and subject and the grammar of design, the latter involving number, punctuation, and inflection; and this section will be found by many of our readers the most interesting part of the work. Mr. Edwards's remarks upon duality and plurality will make many persons realise what they have probably not realised—namely, that where pairs exist in the human body the duality has been resolved—e.g., the two hands are really each of them one-half of unity. Humpty Dumpty discoursed to Alice about her face, saying, "Your face is the same as everybody has—the two eyes so (marking their place in the air with his thumb), nose in the middle, mouth under. It's always the same. Now if you had the eyes on the same side of the nose, for instance, or the mouth at the top—that would be some help." "It wouldn't look nice," Alice objected, but Humpty Dumpty merely shut his eyes and said, "Wait till you've tried." Few of us could say offhand why it would not look nice, but having read Mr. Edwards's book we know that such an arrangement would violate the canons of number, punctuation, and inflection.

Mr. Edwards shows less than his usual acumen when he refers to "doctrinaires, according to whose view it is wrong to adopt in England the architectural forms indigenous to ancient Greece or Rome," who "show the same kind of affectation as do those literary purists who go out of their way to avoid all words of Latin origin." To our mind, the architectural forms of Greece and Rome are unsuitable for England on account of climatic differences. Windows are a monstrosity in a classical building, and so is a high-pitched roof, both of which are necessary in a northern climate. It is just as bad to transport northern architecture to a southern climate, as may be learned in Seville Cathedral.

Although we cannot always see eye to eye with Mr. Edwards, we have found his book capital reading. It is well written, widely informed, and often original in a stimulating and pleasing way. Those who study it will find their personal powers of observation quickened and their desire to see things correctly made more keen. In many directions the book will be of particular interest to medical men.

SYPHILIS AND VENEREAL DISEASES.

Fourth edition. By C. F. MARSHALL, M.D., and E. G. FFRENCH, M.D. London: Baillière, Tindall, and Cox. 1921. Pp. 434. 25s.

THIS fourth edition has been revised throughout and a considerable amount of new matter added. The result is a valuable book, for not only does it contain excellent descriptions of venereal diseases and the routine methods of their treatment, but the teaching is practical and should help the practitioner to deal with all the stages of the diseases and their complications. Special emphasis is laid on the necessity of a clinical diagnosis as opposed to a pathological one; the tendency to rely on the pathologist in these days is great, and it is refreshing to find responsible writers who urge the medical man in charge of a case to begin by using his own powers of observation. The pathology, however, is not neglected.

The authors hold, and we agree with them, that a case of syphilis should not be submitted to a routine treatment, but that more attention should be paid to each individual, whose temperament, amongst other things, requires to be fully studied. A long course of mercurial treatment is strongly advocated; reliance on the arsenical preparations has been carried too far. The advantages and disadvantages of the various methods of treatment are fully discussed. The desirability of using potassium iodide in preference to any of its substitutes is emphasised; at the present stage of our knowledge there can be little doubt as to the wisdom of this advice. In common with most syphilologists the authors believe that the harmful effects of salvarsan have been much exaggerated. They attribute the ill-effects to the improper surroundings of the patients, and especially to a cold atmosphere; but as in most large clinics salvarsan treatment is used on out-patients at all times of the year, while the cases of poisoning are not numerous, we do not find this idea quite probable. Intramine is found to be a useful drug in the treatment of salvarsan poisoning.

Congenital syphilis receives adequate consideration; the diagnosis and treatment of gonorrhœa in all its stages are thoughtfully set out, but the tests for establishing the fact of cure are not very clearly described and might in future editions be elaborated. This book is deservedly popular. It is well got up and the illustrations are adequate.

ESSENTIALS OF MEDICAL ELECTRICITY.

Fifth edition. By ELKIN P. CUMBERBATCH, M.A., B.M., B.Ch. Oxon., M.R.C.P., Medical Officer i/c of the Electrical Department, St. Bartholomew's Hospital, &c. London: Henry Kimpton and Co. 1921. Pp. 388. 10s. 6d.

WE welcome a new edition of Dr. Cumberbatch's excellent book on medical electricity. Since its modest beginning in 1905, when the whole subject was in a state of flux, each succeeding edition of this work has steadily progressed in value. During this period the theory and practice of electrical work in medicine have undergone modifications, to an extent appreciable when we compare the present edition of Dr. Cumberbatch's treatise with the first edition—indeed, the development of medical electricity can be traced through the series.

This last volume differs in no essential particular from those that have gone before. The necessary additions have been made. Treatment of deep-lying organs has been reconsidered in view of the growing belief that it is not possible to introduce ions far below the surface by the galvanic current. It is far more probable that the good effects of such applications are due to a shifting of the ions within the tissues than to any introduced from without. Reference is made to the use of slowly varying currents, including the variety known as three-phase, where the variations between three electrodes follow a regular progression. The author's valuable work on diathermy is here brought up to date, with the addition of notes on the treatment of gonococcal infection by raising the temperature of the affected parts.

The book in its present form remains a handy and safe guide to the medical application of electric current.

DIE CHIRURGIE DER PERIPHEREN NERVENVERLETZUNGEN.

Mit besonderer Berücksichtigung der Kriegs-Nervenverletzungen. Von Privatdozent Dr. WALTER LEHMANN. Berlin: Urban and Schwarzenberg. 1921. Pp. 270. M.81.

THIS monograph combines the author's own experience of injuries of the peripheral nerves during the war, with a critical review of the methods and results of other surgeons in Germany. In size it is comparable with Tinel's well-known "Les Blessures des Nerves," but, as is natural in a work written after rather than at the beginning of the war, it devotes a larger space to treatment and results than to clinical syndromes. The book contains three parts, which are divided into 11 sections and 38 chapters. The first part deals with the pathological and clinical sides of nerve injuries, the second with prognosis, treatment, and results, and the third with ætiology, symptoms, and treatment of injuries to special nerves. A list of 660 references arranged under the number of the chapter to which they belong occupies 30 pages at the end of the book. The literature quoted is almost entirely German, only nine foreign contributions being included. Although 319 of the papers referred to were written during the war, no reference is made to any foreign journal later than 1910.

On the whole, the problems of this chapter of war surgery seem to have been dealt with on the same lines as in this country, and with very similar results. In the section on Prognosis and Treatment of Nerve Injuries and their Results a chapter is devoted to the various materials and methods used for protecting nerves suture or freeing. Calf's artery, prepared by the formalin method of Foramitti, is spoken of favourably, and seems to have been widely used in Germany. One section is devoted to the operative methods for bridging large gaps in nerves and their results. Gradual lengthening and suture by means of a two-stage operation is praised, but no ultimate results are quoted. As in this country, there have been only a few successful end results from nerve grafting and similar procedures. An extraordinary implement called a nerve winder, designed by Bethe, for gradually stretching a nerve is depicted on p. 130; the obvious defects of this apparatus are pointed out by Dr. Lehmann.

This work does little to advance our knowledge, but should nevertheless be read by those who wish to know what has been done in Germany in this branch of surgery during the war.

INTRODUCTION TO PHYSICAL CHEMISTRY.

Einführung in die Physikalische Chemie für Biochemiker, Mediziner, Pharmazeuten und Naturwissenschaftler. Von Dr. WALTHER DIETRICH. Berlin: Julius Springer. 1921. Mit 6 Abbildungen. Pp. vi. + 106. M.20.

IN this volume the subjects of osmosis, dissociation, equilibrium, hydrogen-ion concentration, surface phenomena, and colloids are discussed in a very elementary fashion, evidently as introductory to a fuller study at a later date in the student's course. The subject-matter is usually adequately treated in our text-books of physiology and biochemistry, and medical students at least will hardly need another account. The chapter on hydrogen-ion concentration may, however, be of assistance, for students generally find it difficult to get a clear understanding of this very important part in the life processes. The chapter on surface phenomena may also be read with advantage. Otherwise we may say that the description of osmosis is far too long and of colloids far too short.

CHEMISTRY OF ENZYME ACTIONS.

By K. GEORGE FALK, Harriman Research Laboratory, Roosevelt Hospital, New York. American Chemical Society Monograph Series. New York: Chemical Catalog Company, Inc. 1921. Pp. 136.

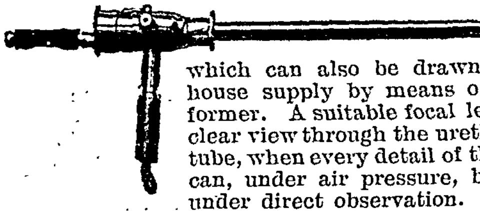
IN this monograph the author discusses enzyme action from a chemical rather than the more usual physical standpoint. As enzymes are catalysts produced by living matter, they should, of course, be studied from both aspects. Special emphasis is laid upon the chemical nature of enzymes themselves. The purest preparations have always been found to contain nitrogen: most enzyme preparations contain about 15 per cent. of nitrogen, but sucrase is an exception in its content of about 2 per cent. only. Horse radish peroxidase appears to be a nitrogenous glucoside. Even though we cannot as yet locate enzymes amongst a definite group of organic compounds, an idea may perhaps be gained of the chemical structure of that part of their molecule which is effective in producing the catalytic action. In this connexion special study has been made of the action of lipase, and we can locate its action in the $CO-NH$ grouping of proteins and its tautomeric form of $C(OH)=N-$. The chief factor in enzyme action is adsorption with the substrate or products of the reaction. Instead of adsorption being a purely physical process, the author regards it as being primarily a chemical one, corresponding to the addition process of general chemistry. Combination only occurs if the chemical groups can interact to form the adsorption compound.

These are the chief points in the book, though other chemical analogies are mentioned as of some possible importance. They might with advantage have been veloped at greater length, and less space devoted to e pure physical chemistry. The long preamble to ery chapter with constant repetition of contents of evious chapters is quite unnecessary.

New Inventions.

THE G.P. URETHRAL AURORASCOPE.

THE instrument here illustrated is not original, as similar instruments in the main are fairly well known to specialists. The head of the instrument contains an electrical circuit leading to an internal lighting bulb. The light is obtained by means of a simple dry battery of 3 to 4 volts power, which can also be drawn from the house supply by means of a transformer. A suitable focal lens gives a clear view through the urethral metal tube, when every detail of the urethra can, under air pressure, be brought under direct observation. The head is also fitted with a stop-cock through which the urethra is inflated by means of rubber bellows. By interchanging the eye-piece for one of my own design a probe of cotton-wool can be moistened with any caustic and passed through the opening in the lower segment of the operating optical eye-piece. The exact location of the disease being in view, direct pressure is made on the proximal end of the probe, which allows sufficient play for the distal end to protrude through the urethral tube and touch the diseased area. Various sizes of urethral tubes are supplied.



The instrument will do the work of the most expensive urethroscope, and has been made for me by the Aurorascope Co., Ltd., Fulwood House, Fulwood-place, Holborn, W.C., where it can be seen and tested. The price is £4 4*s.*, operating optical eye-piece 10*s.* 6*d.* extra, and it is fitted in a leather pocket-case measuring 9 × 4¾ × 1 inches.

HENRY DUTCH, M.D.

CARNEGIE UNITED KINGDOM TRUST.

THE seventh annual report of the Carnegie United Kingdom Trust has recently been issued, dealing with the year ending Dec. 31st, 1920. During this period the work of the Trust was considerable, for although conditions were still very different from those of pre-war days (notably as regards building operations), there was an improvement on the stagnation obtaining in 1919. The section of the report devoted to physical welfare deals with the subject under four headings—central institutes, play centres, model centres, and published reports. With reference to the trustees' offer to provide £40,000 each for two central institutes for infant and child welfare, the report states that local difficulties have prevented action in Edinburgh, but that preliminary steps had been taken towards the establishment of the London institute; the only practical alternative to abandonment of the whole project was found to be the securing of a leasehold property (No. 117, Piccadilly), a building suitable for the purpose and conveniently situated, to house the Central Institute proper, together with its constituent child-welfare societies, and probably also the Incorporated Institute of Midwives. The grant of £40,000 will cover the whole cost of lease, equipment, and sinking-fund charges. Grants have been promised for six model centres, one of which—the Motherwell centre—is now in course of erection. Plans have been passed for the Shoreditch, Birmingham, and Liverpool centres, and it is hoped that building will soon be possible in these places. The plans of the Rhondda centre will probably shortly be submitted, the difficulty of obtaining a site having now been overcome; political and social conditions have prevented any movement to establish the Dublin centre, and the corporation of the city may invite the trustees to modify the project or abandon it altogether—a course which would be particularly unfortunate, since child-welfare work is very urgently required in Dublin. Very few applications have been received for the establishment of play-centres, and some of them when received had to be refused, as the centres were to be administered by voluntary bodies and not by competent local authorities. A considerably increased grant has been approved for the Blackrock centre, and a provisional grant has been promised to the Borough of Norwich. At Chester it has been decided to acquire a new site for the projected centre. It has been decided that two further reports might usefully be published—one, a summary of laws dealing with powers of local authorities regarding physical welfare; the other, a report on the ideals to be aimed at in setting up child-welfare centres—and their preparation is under consideration.

THE LANCET.

LONDON: SATURDAY, MAY 21, 1921.

The Ministry of Health.

AT the end of last week Sir ALFRED MOND, on the vote to meet expenses in connexion with the Ministry of Health, made a statement in respect of the present position and future intentions of his department, which has produced an excellent effect both within and without the House of Commons. For although the sum asked for was a very large one, the explanation of huge work ahead of the Ministry of Health led to an agreement to the vote without any damaging criticism, while the public learned that the Ministry has been, and is, working along definite lines to promote and correlate efforts in behalf of the public health. Considering the vague and various attacks that have been made on the Ministry of Health for political purposes from its quite early days, this may be regarded as a very healthy state of affairs; as the public ignorance, which has been exploited by irresponsible public statements, disappears, the real economy of spending money in the prevention of disease will become clear.

The Minister of Health began by pointing out the perfect absurdity of drawing any comparison between the estimates in connexion with the Local Government Board in and before 1914 and those of the Ministry of Health at the present moment. All such comparisons have been transparent nonsense to those who know, and remember, how the Ministry of Health came into being, and what numerous activities it represents other than those of the old Local Government Board. Nor is this the whole story. New programmes of work, considered by neither the old Local Government Board nor by any of the departments whose functions have been transferred to the Ministry of Health, have been added to the designs of the Ministry, while the administration of the National Insurance Commission, which was dislocated by the war before it had received proper trial of its possibilities, has called for large reconsideration. And if comparisons between the numbers and spheres of work of the medical staff of the old Local Government Board and that of the new Ministry of Health cannot be drawn, it becomes waste of time to debate whether that medical staff, when alluded to as "medical officers," implies only "medical officers" as distinct from "medical inspectors," or implies the medical staff as a whole. In the House of Commons Dr. ADDISON stated, during the debate, that under the Local Government Board in 1918 there were already 38 medical officers. The statement was perfectly true, and not a person ought to have been deceived into thinking that he meant 38 heads of groups and sub-groups, under whom medical inspectors worked. He was clearly including the "medical inspectors" under the term "medical officers," as is always done in conversation.

The actual figures, which can be fairly compared in order to show the relative position of the headquarters staff of the Ministry of Health in 1918 and to-day, are as follows:—

1918.		*1921.*		
Medical Officer	1	Chief Medical Officer ...		1
Assistant Medical Officers	5	Senior Medical Officers...		6
Medical Inspectors	23	Medical Officers—		
		General	43	50
Med. Inspectors of Food	5	Food...	5	
Med. Inspectors Poor-law	2	Poor-law	2	
Med. Bacteriologists ...	2	Med. Bacteriologists ...		2
	38			
Insurance Medical Officers	8			
	46			59

Here is Sir ALFRED MOND'S statement on the matter, and it will be seen that it tallies both with the facts and with Dr. ADDISON'S figures:—

> On April 1st, 1919, the number of pensionable medical men in the Local Government Board and the Insurance Commission of England and Wales was 46; the number at present in the Ministry is 59, or a difference of 13, distributed as follows: Maternity and child welfare, 2; tuberculosis, 2; venereal disease, 2; port isolation hospitals, 3; statutory medical services and intelligence work, 3; and work taken over from the Home Office, 1. These are additional functions to the work which is being looked after by the medical staff of the Ministry of Health, apart from the newly established regional officers. There are no less than 1800 sanitary authorities which look to the Ministry for guidance, 114 port authorities, 646 Poor-law unions, 1029 isolation hospitals for infectious diseases, and 4220 public vaccination districts which have to be inspected. There are a vast number of maternity centres and tuberculosis sanatoriums to which the Ministry give grants and which also have to be inspected.

This statement, which will be found in our Parliamentary Correspondent's report, should be remembered, when, in the future, the wholesale cutting down of the members of the medical staff of the Ministry of Health is under discussion on the score of economy. Colonel FREMANTLE, during the debate in the House of Commons, alluded to "a canard going round the press that the Ministry of Health inherited from the Local Government Board a staff of only four medical officers." He has since written to the *Times*, where the unfortunate announcement was made editorially in the course of a plea for economy, giving much the same comparative figures as those we print above. All advocacy of economy is welcome to-day, but its basis should be correct.

Three expressions of opinion and intention came from the Minister of Health, which revealed to the House of Commons a story of strenuous industry. He claimed that in spite of difficulties the department had succeeded in making a reduction of over £3,000,000 in the estimates of this year as compared with last year, while considerable progress had been made with housing schemes. And here he pointed out—what is now well known—that some local authorities have exaggerated local wants. The national need is grave enough without such troublesome errors. Secondly, in reply to points raised principally by Sir WATSON CHEYNE, Sir ALFRED MOND stated that there was no intention on the part of the Government to start a State Medical Service, although an endeavour was being made to improve the existing panel systems in certain directions. We may hope that one of these directions will be the encouragement of all movements on the part of the Approved Societies to assist in the support of the voluntary hospitals. It was announced, on the very afternoon that the Minister of Health was speaking, that a number of beds in the London Hospital would have to be closed, and the Minister allowed that the position of these great charities was giving his department cause for anxiety; but recent action by the Approved Societies should have an encouraging influence here. These Societies have discussed with the British Hospitals Association the possibility of providing *institutional treatment for their members*, who form so large a section of the panel patients, in return for contributions on an agreed percentage basis, and if the voluntary system can be supported in this way on any general plan the relief to the charities should be great and promptly felt. Lastly, Sir ALFRED MOND defended the policy of the Government in respect to venereal disease, a policy directed towards official propaganda, but also towards the promotion of treatment. While he stated that he refused to accede to any demand to regard the question from a merely medical point of view, it is well known that a comprehensible policy in respect of the control of venereal disease, *taking note of* the therapeutic side, will shortly claim public attention. There is nothing new about such a policy, but for various reasons it has not been pressed forward by the Ministry, and medical men will agree that it is difficult, dangerous, and sometimes wrong for a Government department to lay down from the centre rules which cover therapeutic details. Indeed, it can be argued that a Government department acting along such lines would be "prescribing by correspondence," the mischief of which has been sufficiently illustrated by countless charlatans. Further, the Ministry of Health is bound to take into consideration the freedom of opinion of the local authorities working beneath its ægis. For this reason the Ministry can hardly go further in the definite treatment of venereal disease than to acquiesce in freedom of action on the part of those who represent the ratepayers. But medical men have learnt with pleasure that, in view of the prevalence of venereal disease, the Ministry proposes to offer public advice, pointing out the duty which lies on all individuals infected to take measures to purify themselves. It need hardly be added that those measures must be sufficient and must be prompt, or they will only constitute an imitation of protection. The duty of the Ministry is to help those who desire to help themselves; and the duty of the local authorities is to come promptly to a decision as to the methods which can be employed to such an end.

◆

Prague as a Health Focus.

HEALTH conditions in Prague under imperial rule left much to be desired. It was difficult to obtain a trained nurse. In the large part of the town the drainage was inadequate, and the rough stone-paved streets in the older quarters were not kept free from garbage. Things are apparently improving. Set in the very midst of the European storm circle, the Czecho-Slovak Republic enjoys none the less some measure of the peace essential for any organised health effort. A number of voluntary health and social organisations have long existed in the Republic without any contact between each other, and now, at a meeting called by the Czecho-Slovak Red Cross, representatives of nine of the most active of these organisations have arranged to meet on a council in whose deliberations public health and social effort shall have their fitting place. Each organisation will preserve its independence, the council meeting four times a year for joint deliberation. A central office with a part-time secretary in the building of the Red Cross provides for the collection and circulation of information. The generosity of the International Health Board of the Rockefeller Foundation has made it possible to open this office at once on an experimental basis.

At the same time the Ministry of Public Health and Physical Education is making every effort to mobilise all forces against the spread of infectious diseases. This is a measure of wise precaution, although the general situation in Slovakia itself is not alarming. Neither the typhus epidemic nor the small-pox epidemic which were anticipated for the spring fulfilled the gloomy promise, and of the latter only scattered foci persist in Slovakia. No cholera has been reported. The Ministry has at its disposal a *mobile column to fight epidemics*, consisting of four motor-cars, one containing a laboratory, a second to accommodate personnel, a third for transport of patients, and a fourth containing disinfecting plant. Four nurses are attached to the unit, the chauffeurs are trained disinfectors, and a physician is in charge of the whole. The unit will at first operate in Slovakia along with a sanitary train lent by the American Red Cross to the Government. Proceedings will be made easier later by the passage into law of a Bill now before the Assembly for the administration of local health under a national service of officers. The measure was deemed necessary in order to secure an adequate medical and public health service for Slovakia, where the peasants are ignorant and greatly in need of medical and health services although unable to support their health officer locally. The nationalisation of some two thousand part-time health officers will increase the budget of the Ministry of Health by about 50 million crowns, but it will make it possible for the Ministry to send to Slovakia young Czech doctors who otherwise would not go there because they could not support themselves by private practice.

At the Ministry itself a new section has been organised for the study and reform of public health activities. The first task of this section will be to demonstrate the value of statistics and public health education in the programme of a would-be modern State. The section has two chiefs, one of them being Prof. SELSKAR M. GUNN, technical adviser to the Ministry, who represents the Rockefeller Board; the other Mr. KOLÍNSKY, who returned recently from a study trip to England and the United States under the auspices of the same Foundation. The personnel of this section will chiefly consist of doctors who have spent a year studying public health administration in the United States. An advisory board consisting of prominent men in the field of public health in Czecho-Slovakia has been attached to the section. The whole movement will be watched with sympathetic interest by the neighbours of the Republic, near or remote, who would like to see at Prague a health centre from which the infection of true hygiene may radiate out into lands where plague centres are the rule. We hope the Little Entente, as the understanding between Roumania, Hungary, and Czecho-Slovakia has been termed, has included in its understanding a concerted campaign against epidemic disease.

Rickets and Vitamins.

IN the April number of the *British Journal of Experimental Pathology* Professor D. NOËL PATON and Mr. A. WATSON, after a brief recapitulation of their previous work on the subject, give a detailed account of further experimental investigations into the ætiology of rickets in pups. They use throughout pups from the same litters for comparative tests, as, in their opinion, the susceptibility of different strains is so varied as to invalidate statistics collected except on this principle.

The object of the first of the new series of experiments recorded has been to test the possibility of rearing dogs free from rickets, when confined in a laboratory, on diets: (1) rich in milk-fats, and (2) poor in fats supposed to contain an antirachitic factor. Both sets of pups developed rickets, but those on an abundant diet less rapidly. In order to ascertain whether this delay could be attributed to a decrease in susceptibility due to more ample energy intake, apart from the influence of any accessory food factor associated with milk-fat, a second series of experiments was undertaken. Pups from three litters were divided into four classes, in each of which the energy intake was kept ample throughout the whole period of growth mainly from one of the following sources: (A) Whole fresh milk and bread (2 pups); (B) whole dried milk and bread (3 pups); (C) separated milk, bread and lard (4 pups); (D) separated milk and bread (9 pups). Two of the pups in Class D were kept in a large kennel with an open yard, and were freely exercised every day; and in order to try and hasten the onset of rickets two others, also in Class D, were kept in a rabbit hutch from the age of 12 weeks to the age of 16 weeks. The rest were kept in a laboratory, a large sunny room with a concrete floor, in movable pens measuring 5½ ft. square. Very special precautions were taken to ensure cleanliness. Of these pups, one, in Class B, died at the end of the ninth week of the diet, not from rickets. One only, in Class D, of the remainder developed rickets. The conclusions drawn from these experiments by the authors are as follows:—

(1) In young dogs under ordinary laboratory conditions a liberal allowance of milk-fat, up to even 14 g. daily per kilo of body-weight, does not prevent the onset of rickets.

(2) Pups kept largely in the open air may escape the development of rickets on an intake of less than 1 g. of milk-fat per kilo of body-weight.

(3) With scrupulous care as to cleanliness it is, at least sometimes, possible to rear pups free of rickets in the laboratory on an intake of only about 0·5 g. of milk-fat per kilo of body-weight, along with bread, provided that the diet affords an adequate supply of energy.

(4) The energy value of the diet, however supplied, quite apart from the presence of any hypothetical antirachitic factor in milk-fat, would seem to play a part in controlling the development of rickets; but that it is only a contributory part is shown by the development of rickets in pups with a high energy intake if confined in the laboratory without scrupulous care as to cleanliness.

(5) Milk-fat may be reduced to about 0·3 g. per kilo of body-weight, if its place is taken by an equal amount of lard, without the onset of rickets.

(6) The results of these observations give no support to the conclusion of the Accessory Food Factors Committee of the Medical Research Council that rickets is a deficiency disease due to a lack of an antirachitic factor in the diet.

Much work on accessory food factors has been done since the publication in 1919 of the report referred to. With more knowledge distinctions have become less absolute. For example, Professor E. MELLANBY,[1] referring to the observations of HESS and UNGER, emphasises the difference in distribution of the fat-soluble factor and the so-called antirachitic factor in vegetable fats. He says that though cotton-seed oil is generally accepted as containing no fat-soluble A, in his experience it is one of the better vegetable oils in preventing rickets. And investigators are by no means agreed even on the presence or absence of fat-soluble A in any given foodstuff. Professor PATON, following most authorities, assumes that lard is considered vitamin-free, while quite recent work by Dr. J. C. DRUMMOND[2] differentiates between lard derived from grass-fed pigs and those fed on a diet deficient in vitamins. In the former he has found fat soluble A. Incidentally Professor PATON deduces from the first experiment quoted above that for experimental purposes "dried milk may safely be substituted for fresh milk." Dr. DRUMMOND classes their relative content of fat-soluble A as ++ and +++. Since quantitative results that cannot be expressed numerically are of doubtful value, not even the firmest adherents of the vitamin hypothesis could regard this as an important contribution to the question of the form in which milk ought to be supplied to children. We only mention it as a further sign of what an enormous mass of work yet remains to be done before the presence or absence of a vitamin from any foodstuffs, still less the ætiology of rickets, can be proved. In fact, those who are inclined to be quite bewildered by the conflicting results of different eminent observers in the same field can derive some help from a critical essay by T. B. OSBORNE and L. B. MENDEL.[3] These authors draw attention to the contradictions existing in the literature as to the presence or absence of a fat-soluble vitamin in a given experimental diet, and are inclined to attribute the discordant results of various workers to traces of this vitamin in certain diets generally considered free from them. However, they agree with Professor PATON in emphasising that the crucial experiment in which nutritive failure ensues immediately upon giving a diet deficient in this respect has not yet been done. They might have gone even further. Until a more accurate quantitative basis of estimating vitamin content can be attained the question must remain unsolved.

[2] Maternity and Child Welfare, May, 1921.

[3] Jour. Biol. Chem., 1921, 45, 277.

LONDON INTER-COLLEGIATE SCHOLARSHIPS BOARD.—Seventeen medical entrance scholarships and exhibitions of an aggregate total value of about £1590 will be offered for competition on Tuesday, June 28th. These are tenable in the faculty of medical sciences of University College and King's College, and in the medical schools of Westminster Hospital, King's College Hospital, University College Hospital, the London (Royal Free Hospital) School of Medicine for Women, and the London Hospital. Particulars may be obtained from the secretary of the Board, S. C. Ranner, M.A., the Medical School, King's College Hospital, Denmark Hill, London, S.E. 5.

Annotations.

"Ne quid nimis."

PURE AIR ON COMPULSION.

WE print in this issue a further instalment of monthly records of atmospheric pollution taking the risk of being convicted of a certain grim humour, for, with the disappearance from our cellars of the last fragment of bituminous coal, atmospheric pollution has become as extinct as jail fever or the black death or any such avoidable mediæval nuisance. The records show that in May of last year ten tons or more of solid matter descended on each square kilometre of the industrious metropolis, half a ton of this material consisting of tar and a further two or three tons of other carbonaceous matter. This present month of May, what dust there is in London has become clean like country dust, the rain descends without flecking with soot every white object on which it falls, and the famous vista along Park-street—Portman-street—Gloucester-place ends with a glimpse of the northern heights of almost Italian clearness. At the Meteorological Office the newest instrument has been rendered useless. This constrains London air to make its own dirty record, two litres of it being drawn through each of a number of small circles in a disc of blotting paper, which revolves once in 24 hours, the tint of the resulting stain being read off on a scale. The last week or two the stain is not there to estimate. In Manchester, where smoke is alleged to cost the citizens each year a million pounds in laundry alone, the whole aspect of the place has changed and cheers some of the oldest inhabitants with views unseen for half a century. These are the evidences which must needs bring conviction to the great public whom figures do not touch. The right place for products of incomplete combustion is in our chemical and dye works, where they are badly required. There is no sense in polluting with them the air we breathe, and now that city dwellers have been obliged by dire necessity to breathe pure air for a few weeks we may hope that they have acquired a taste for it which will survive the momentary crisis.

THE LOST ART.

IN his special pharmacopœia for medical men Sir James Mackenzie carries some stimulating drugs and some useful tonics, which though they may be a little bitter to the taste are certainly good "strengthening medicine." It is not pleasant hearing that during the last 100 years practically no progress has been made in the recognition of the origin of common diseases, nor that the art of prognosis, so important to the patient, has actually retrogressed; but these implications as expounded by Sir James Mackenzie are not easy to refute. The description of a specialist as an expert only in the treatment of the later stages of his speciality is hardly unfair, while the cherished belief of the public that accurate prognosis is within the power of the average medical man is belied not only by life insurance practice but in everyone's daily experience.

In his recent lecture at the Institute of Pathology and Research at St. Mary's Hospital. Sir James Mackenzie disclaimed at the outset any desire to belittle laboratory methods, of which he appreciated both the value and the limitations—and, indeed, his indictment of the laboratory worker was less severe than his censure of the training and the habits of the modern clinician. The training of the latter for his special work has, in truth, suffered grievously with the alteration of the medical curriculum during the last 10 or 15 years. The final years are almost intolerably crowded. Whereas in years gone by the student could spend, and was encouraged to spend, long hours in the wards studying his cases, he has now to pass in hectic progression from one class room to another. Every specialist, with the laudable fanaticism of his kind, insists on the importance of his subject, and demands that special courses of instruction should be made compulsory. In the sacred name of progress fresh claims are constantly being made on the remnants of the students' eight-hour day, and it is not difficult to visualise a future in which the medical graduate shall be so fully trained in every ancillary science pertaining to his art as to be able to do everything except apply his knowledge to the treatment of a patient. The thoughtful clinician is fully alive to the dangerous possibilities of such a state of affairs and from time to time complains that his art has been relegated to a position of secondary importance. But he himself cannot be absolved from blame. Fascinated by the new knowledge he has attempted to teach and practise it, not always with complete success, and in doing so has lowered his own calling. He has failed to maintain the paramount importance of clinical work, and to assume the position of interpreter of information supplied him in different languages by his colleagues. He has been prone to regard the laboratory worker as a machine who is there merely to give him a plain Yes or No to a plain question, seldom as a colleague consultant in the sick room. The consequence is that the clinician has lost or is losing his art, while the specialists are not placed in a position collectively to supplant him, even if that were possible or desirable. Sir James Mackenzie spoke somewhat slightingly of team-work, but real team-work should certainly have a trial, at least in teaching hospitals, before being condemned. Men who work in the laboratory must be encouraged to the bedside, since medicine cannot be divorced from the patient. We suspect that Sir James Mackenzie is not interested in experimental team-work mainly because he considers that the general practitioner, who cannot as yet obtain the advantages of proper collaboration, is being wrongly trained. He is asked to study physical signs instead of symptoms, to keep records of little value, to take meaningless histories. He cannot be taught what symptoms mean, which records are important, and how to take a valuable history. But this want of knowledge Sir James Mackenzie has set himself to supply, at least in part. In describing his efforts in this direction he delighted his audience with anecdotes at the expense indiscriminately of himself, of his guests at St. Andrews, and of his hosts at St. Mary's. In more serious vein he demonstrated the ways in which modern medical research had, in his opinion, taken a wrong turning, and this was the main theme of his discourse. Shrewd and yet kindly were his attacks on modern methods of medical education, their essential message appearing to us to be that the student requires more general and sympathetic shepherding along the course than he receives to-day.

ABRUPTIO PLACENTÆ.

ACCORDING to Dr. Edgar Snowden,[1] assistant obstetrician at the Columbia Hospital, Washington, who records an illustrative case, abruptio placentæ, or hæmorrhage occurring from premature separation of a normally implanted placenta, is one of the most serious complications of pregnancy. It was first described as long ago as 1776 by the elder Rigby, but it is only recently that its pathology has been studied with any degree of scientific exactness. The condition probably occurs more frequently than is generally supposed, as many mild cases pass unrecognised. According to statistics at various maternity hospitals its frequency varies from 1 in 92 (Rotunda, Dublin) to 1 in 600 (Chicago Lying-in Hospital). The most recent investigations show that toxæmia is the primary cause of the condition, the toxin being possibly of placental origin as suggested by Willson. The hæmorrhage may be apparent, the blood escaping under the edge of the placenta or through the cervix into the vagina, or it may be concealed, the blood accumulating in the retro-peritoneal space and infiltrating the muscle fibres, thus causing uterine atony, or it may rupture into the amniotic sac. The hæmorrhages which are small at first coalesce and extend to the tubes, ovaries, and out into the broad ligaments. Bloody fluid may be found in the peritoneal cavity probably coming from small fissures in the surface of the uterus. In a typical case the onset is sudden and violent, the severity of the symptoms depending on the degree of the separation. The patient who is in the last three weeks of pregnancy complains of a sudden abdominal pain of a colicky nature and soon shows signs of acute anæmia, followed by shock. A bloody vaginal discharge may or may not appear. On examination the uterus is found to be larger than usual, very tender, and of a peculiar wooden consistency. No placenta can be felt per vaginam. Treatment consists in emptying the uterus as soon as possible by forceps, version or Cæsarean section, stopping the hæmorrhage, and combating the anæmia. In some cases hysterectomy may be required. The prognosis is very grave, the maternal mortality being about 60 per cent. and the fœtal mortality about 90 per cent. Cases which survive require the utmost care and attention.

SURGERY OF THE THYROID GLAND.

IN the April number of the *British Journal of Surgery* Mr. James Berry gives an account of a series of 500 operations for goitre, with special reference to the after-results. The youngest patients were five girls of 14 years of age, who had parenchymatous goitres. Operations on children under puberty were only undertaken when urgent, for in the young there is danger of interfering with growth and normal development. The oldest patients were seven males between 70 and 75 years of age. The two commonest forms of goitre operated on were the non-encapsuled adenoparenchymatous, 137 cases, and the encapsuled cystic adenomatous, 109 cases. Seventy-nine operations were for true exophthalmic goitre as distinguished from "false" exophthalmic goitre. In the latter there is tachycardia, tremor, &c., without exophthalmos, mostly with unilateral goitre. Sometimes true exophthalmic goitre develops in a patient who has previously had an ordinary goitre for a more or less long period. Twelve cases of malignant disease were operated on, these being selected from a large number of cases of malignant disease which were seen. Of the cases operated on, two were sarcomata, one undetermined, and the others carcinomata of various types. The indications for operation were chiefly dyspnœa (274), discomfort and deformity (99), and exophthalmic goitre (79). Tracheotomy was never performed for innocent goitre, and is considered to be much more dangerous than thyroidectomy. But when dyspnœa is urgent a long tracheotomy tube, such as Koenig's, should be at hand. With bilateral goitre and severe dyspnœa it is often dangerous to rely on a unilateral operation. If only one lobe is removed, the other may bend the trachea to the opposite side and increase the dyspnœa. An important practical point is that often it is not the most obvious and prominent part of the goitre which is the cause of the dyspnœa. The real offending part is not unlikely to be the opposite lobe lying more deeply, perhaps wholly unsuspected, behind the sternum. An X ray examination is often useful in showing which part of the trachea, appearing as a band of light, is most deflected. In the young with bilateral goitres it is usually the least prominent lobe which causes the dyspnœa. The lower the situation of a goitre, the more liable it is to produce dyspnœa. Discussing the methods of operating, the writer remarks that he has never performed total removal of the gland and that he considers it unjustifiable and never necessary even for malignant disease. He rarely performs total removal of even one lobe. A portion of gland is nearly always left at the hilus, or "dangerous area," for various reasons, one being to safeguard the recurrent laryngeal nerve. Seven patients died from operation: two of them had simple goitre and succumbed some days later to pneumonia; three had exophthalmic goitre and died from cardiac failure; two had malignant goitre. Recurrent laryngeal nerve paralysis is known to have occurred three times. It is sometimes unavoidable in large, deep-seated tumours. The nerve lies in front of the groove between the trachea and œsophagus. It may be pulled forward with the gland when operating and is most likely to be injured at a level a little below that of the lower border of the pharynx.

An important table given is that showing the late results in 406 cases. The patients with simple goitre are nearly all well and in much better health than before operation. Of the 78 patients with exophthalmic goitre 53 are practically well, 18 much improved, 1 improved, 2 not improved, 1 worse, and 3 died. All were operated on before Dec. 31st, 1919, and 24 of them in 1913. Complete cure in this disease, with no trace of the previous symptoms remaining, is rare. Often a considerable amount of exophthalmos remains in patients who consider themselves otherwise well, and they may have palpitation on exertion. The operations are considered to be much more dangerous than most operations for simple goitre. The patients are often quite unsuitable for operation when brought to the surgeon. In some ligation of one or both superior thyroid arteries will give great relief. The condition of the myocardium is a very important factor in prognosis. Relapse may occur after a long period of good health. Of the 12 patients operated on for malignant goitres, 5 are living and well after periods of 1¼ to 7½ years. One is fairly well but with recurrence 1½ years after operation. Four have died from recurrence within a year, and 2 died from the operation. There has been no marked myxœdema in any of the author's cases. In a few, chiefly of extensive bilateral removals, there have been slight transient symptoms of thyroid insufficiency and the patients have benefited from taking thyroid extract. Tetany has never been seen by the author to follow operation for goitre, though he has operated 1338 times, and he is sceptical as to the separate function of the parathyroids.

We have closely followed Mr. Berry's own account of his experience, which adds a new and useful chapter to the literature on the practice and principles of this branch of surgery.

THE ROYAL SOCIETY EXHIBITS.

THE annual conversazione of the Royal Society was held at Burlington House, London, on May 11th, when Fellow demonstrated to Fellow such portions of new and original work as lent themselves readily to isolated treatment, the interest centring round the light thrown upon natural law rather than upon its application to human need. Medicine as the most highly specialised of sciences was consequently little represented. Mr. J. E. Barnard showed how certain animal tissues reveal marked differentiation of structure when illuminated by means of ultra-violet light. The image obtained is a fluorescent one and the resulting colours or tints depend on differences of chemical constitution. Apart from the biological interest of the method the image so formed is of considerable value for testing the optical qualities of microscopic objectives as the object so illuminated is a perfectly self-luminous one. Dr. Leonard Hill exhibited a recording kata-thermometer. This instrument gives a continuous record of the cooling power of the environment exerted on the surface of the bulb of the kata-thermometer, which is automatically kept at skin temperature. Introduced into the bulb of the "kata," which is filled with alcohol, is a coil of wire with a large temperature coefficient of resistance. This coil forms one arm of a Wheatstone bridge, which is balanced when the coil is at a temperature of 36·5° C. An automatic device is used by which the current sent through the coil varies according to atmospheric conditions, so that the coil is kept at 36·5° C. The ammeter placed in series with the coil indicates the variations of current and so the cooling power. Mr. L. T. Hogben, from the Zoological Laboratory of the Imperial College of Science, illustrated the effect of pineal gland administration on the pigment cells of tadpoles. Within half an hour the melanophores retract to such an extent as to turn the brown opaque tad into a grey translucent one. No other organic extract has been found to produce this result. Of more practical importance was a demonstration by Mr. Franklin Kidd on the application of cold-storage and gas-storage to English apples. The Food Investigation Board recognises that improved methods of apple storage are required in order to bring the home grown apple into successful competition with imported apples throughout the winter season. In cold-storage the apples are kept just above freezing point. The method is costly. In gas-storage the apples are held in a gas mixture, created and maintained by their own respiratory activity, no machinery being required. The optimum CO_2 pressure has been determined and by its means the life of the apple is prolonged at a lower level of metabolism to twice its normal span. The specimens shown fully bore out this contention.

INTERNATIONAL TEAM-WORK.

COÖPERATIVE effort in medical research has of recent years been productive of so much good and its value is now so widely recognised that no one can doubt that team-work will continue to contribute to the advance of medical science. Yet when all due respect has been paid to the advantages of such coöperation one is forced to admit its limitations. Brilliant as are the results published from that most admirably equipped of all local teams captained by the Mayo brothers in America, it is doubtful whether anything they have produced can rank in practical importance beside the discoveries of such individuals as Koch, Pasteur, or Noguchi. The truth is that local team-work must be compared, not always to its advantage, with individual exploits. For this reason it is well to remember that for many years there have been widely scattered international teams working together with magnificent harmony in the various fields of physical disease. This would not have been possible but for the fine medical tradition that has always prevailed among physicians of every race and creed. It would be inaccurate to speak of the captain of an international team. The inspiration of genius is its sole directing force. But such a team is handicapped unless it possesses at least one member endowed with such critical insight and deductive imagination that he is able to sift the work of his colleagues and rearrange their variously coloured contributions into a comprehensive and cohesive pattern—in short, the value of a captain is as obvious in an international as in a local team. A brilliant example of this will be found in a recent paper on the course of the tubercle bacillus from sputum to the child by Dr. Allen K. Krause, of Baltimore.[1] Dr. Krause first restates the three main theories of the ætiology of pulmonary tuberculosis which may shortly be described as "the dust," the "droplet," and "the ingestion" theories. He argues that from the absence of direct evidence to confirm any one of these theories it is necessary to seek for correlative evidence. Here another group of observers, statisticians rather than pathologists, furnish their contribution. A composite infection chart is built from the charts of Moro (Munich), Mantoux (Paris), Petruschky (Danzig), Gaughofner (Prague), Pirquet and Hamburger (Vienna), Nottiman (Düsseldorf), Veeder (St. Louis), and Armstrong (Framingham). The evidence so collected shows that 10 per cent. of children are infected by the end of their second year of life, by 3 years 15 to 20 per cent., by 6 years 50 to 60 per cent., by 15 about 75 per cent.—i.e., only about one-seventh of all infected receive their first infection during the first two years. If the "droplet" method of infection accounts for all infections, then children must be confined indoors more between the ages of 4 and 7 than between birth and the age of 3. The argument is that infection is most rife at the age when children play amongst the dust both of the house and of the street. The hands of the normal child "are dirty most of the time" and "few children have developed a consciousness about putting their hands in their mouths." Here is a practical moral drawn from the work of two generations of the members of the tuberculosis team scattered across the world. It is a moral that deserves attention.

ACUTE NITROBENZOL POISONING.

ACCORDING to Dr. Robert F. Loeb, Dr. Arlie V. Bock and Dr. Reginald Fitz,[1] of the Medical Clinic of the Massachusetts General Hospital, Boston, who are engaged in a series of studies on the physiology and pathology of the blood, nitrobenzol or oil of mirbane, a coal-tar derivative resulting from the action of strong nitric acid on benzol, was first discovered by Mitscherlich in 1834, but it was not until 1859 that Caspar described it as a new poison with toxic properties. It is employed in the manufacture of high explosives, and is used to a limited extent in perfumery, soap, confectionery, cookery, in making dyes, and in pharmaceutical laboratories. Grandhomme, in 1883, collected 43 cases of nitrobenzol poisoning, the majority of which had occurred a comparatively short time after nitrobenzol had been used commercially. After the appearance of Grandhomme's work only a few new cases were published until two years ago, when Stifel reported 17 cases which were poisoned by nitrobenzol in shoe polish. Subsequently Scott and Hanzlik, Donovan, and Dr. Loeb and his colleagues met with cases in which intoxication was due to nitrobenzol being consumed as a substitute for alcohol. The toxic action of nitrobenzol, as shown by Filehne's experiments in 1878, is due to the fact that it renders the blood unable to transport oxygen. Experiments on dogs showed that hæmoglobin was changed into another form with a characteristic spectroscopic absorption line which did not correspond to any of the ordinary hæmoglobin products. Whether nitrobenzol hæmoglobin, meth-hæmoglobin, or both are produced is uncertain. The clinical picture consists in a gradual onset of nervous and digestive symptoms going on to coma and death, the skin assuming a characteristic blue-black colour. The urine is almost black and contains para-amido-phenol. In cases which recover, the changed hæmoglobin returns to normal hæmoglobin quickly, so that oxygen can again be carried to the body cells in a short time. Although the majority of the recent cases in America have been mild, nitrobenzol may often be a fatal poison, as is shown by the fact that the mortality among Grandhomme's cases was 32 per cent. There is no specific antidote, but treatment consists in as complete and rapid removal as possible from the body of any nitrobenzol which has not been absorbed. Bleeding and transfusion are indicated in the severest cases.

THE "STABILITARY" REACTION OF THE BLOOD.

EVERY laboratory worker who has to collect from patients each week large numbers of blood specimens for fixation of complement tests is acquainted with those curious phenomena which occasionally occur during clotting. Sometimes a blood sample will clot almost as soon as it is withdrawn from the syringe, occasionally it will remain fluid for several hours, occasionally also it shows hæmolysis, and every now and then a specimen is found which produces an almost opalescent serum. Some of these phenomena are doubtless due to mechanical factors of manipulation; but apart from these it seems clear that we are presented with inexplicable stages in that colloidal reaction, coagulation of protein, which is probably due in a large measure to the reduction in the surface energy at the interface of the colloid, and is known biochemically as the adsorption phenomenon. These colloid changes give rise to outward and visible signs such as agglutination and precipitation, altered rate of coagulation, increased or decreased viscosity, and the like; and every one of them has been made the basis of a clinical laboratory test. In the current number of the *British Journal of Tuberculosis* Dr. A. Westergren, of Stockholm, describes briefly the "stabilitary" reaction of blood which depends on the rate of sedimentation of red blood corpuscles in a column of withdrawn citrated blood. Briefly, the test is as follows. The blood is withdrawn from the patient's vein by means of a syringe having one-fifth of the barrel filled with 3·8 per cent. sodium citrate solution. When the remaining four-fifths have been filled with patient's blood the contents are immediately emptied into a small test-tube and well mixed. The mixed blood is then drawn into a pipette-tube 30 cm. long (with an inner diameter of 2·5 mm.) up to a height of 20 cm. and placed in a rack. The time is noted, and the tube allowed to stand for 1, 2, and 24 hours, when the test is read off by measuring the height of the layer of plasma in millimetres from the lower meniscus of the free surface to the upper border of the deposited blood corpuscles. In blood drawn from healthy men the top layer of clear plasma at the end of one hour is said to be 2 mm. and in women 5–10 mm. An increased sedimentation (i.e., a reduced suspension stability of the blood) is found in pregnancy and in acute infectious diseases, especially when associated with much pyrexia. Dr. Westergren finds that this increased sedimentation is markedly shown in cases of acute pulmonary tuberculosis. He says: "No single test of an active or probably active case has given a normal value, and no case which must be considered quite benign, and certainly shows no signs of activity, has given a high, even a middle-high, figure." He therefore considers the reaction to be a more reliable measure of activity than is a temperature record. The reaction is, of course, in no way specific, and can only have a relative value in estimating activity as an aid to diagnosis and prognosis. A full account of this reaction is given in English in *Acta. Med. Scandinavia*, Vol. LIV., pp. 247–281.

SO-CALLED SNOW-BLINDNESS.

SOME interesting notes regarding the pathological effects of the visible and invisible spectrum on the eye, more especially in relation to snow-blindness, are contributed by Mr. Arthur W. Ormond in the April number of Guy's Hospital Reports. These make it plain that both visible and invisible rays can produce definite pathological effects on the ocular tissues, but further inquiry is required to prove the exact wave-lengths which set up these changes. The heavy incidence of cataract in glass-workers—exposed as they are to the intense heat and brilliant illumination of molten glass—led to the suggestion that the heat rays are the cause of the injury in these cases, and the balance of opinion appears to be in favour of this hypothesis. However, more recent experiments suggest that lenticular changes may be produced by ultra-violet radiations. The effects of sunburn are probably due not to visible but to ultra-violet rays. Meantime, we have some interesting first-hand observations by a young officer, a member of a Canadian Arctic expedition, who visited Parry Archipelago and its neighbourhood. To begin with, it is suggested that snow-blindness is "a bad term, as the victim is not blind." The condition was never experienced in extremely low temperatures and seldom at freezing point, but generally in a condition of mist or fog, a fog-haze or "white-darkness" in snow-covered regions when all sense of perspective and stereoscopic vision is lost. Bright sunlight affected the eyes in a different manner, and real blindness was never the result of bright glaring sunlight and shadow. The symptoms of severe conjunctivitis and superficial ulceration of the cornea were pronounced, "grittiness," discharge from eyes and nose, in 24 hours intense local pain—lasting sometimes for 10 or 12 hours—the pain being described as the sensation of thousands of red-hot needles being forced through the eyes to the sockets. The eyeballs and lining of the lids are covered by a greyish film, through which the iris and pupils are just discernible. The sufferer can see nothing, even with the eyes held open. If the eyes are protected by bandages at the first noticeable symptoms, after three days the eyes are practically normal, but there is a tendency to relapse if unfavourable conditions recur. The use of dark or coloured glasses is sufficient protection, but the leader of a party cannot always keep glasses before his eyes; the glasses become dimmed with hoar-frost and have to be removed to be cleaned. The native Eskimos are not immune from attacks of snow-blindness, and Scott and Shackleton observed that dogs and ponies manifested characteristic symptoms. The Eskimo has learned to recognise weather conditions which are dangerous from this point of view and arranges his travels accordingly. When he does travel—rarely more than five miles a day—he protects his eyes with horizontally slotted wooden spectacles cut from soft drift timber; even these are not absolutely preventive. Nansen records that in his Polar expedition only two of his party, who had neglected the necessary precautions, suffered from snow-blindness.

As to the part of the spectrum responsible for the sensations experienced by the victim, we may exclude the infra-red rays; nor is the visible spectrum entirely responsible, for in the tropics, where light is very intense, symptoms such as these are not experienced, and in summer there is no complaint of "snow-blindness" amongst ordinary Swiss tourists. Fuchs, of Vienna, records that some visitors to the Alps after exposure to the snowfields "see red," especially in a dimly illuminated room. The question remains whether snow-blindness can be due to ultra-violet rays alone. During the war an acute condition of the eyes similar to snow-blindness was set up in persons working with a searchlight device elaborated for signalling at sea, whereby all parts of the spectrum except the ultra-violet and a few red rays were filtered out. The effects seem to be due not so much to the quality as to the quantity of these rays. A few of the short rays may penetrate to the lens, but experiment shows that very few ultra-violet rays reach as far as the retina. Retinal symptoms are not amongst those caused by snow-blindness. The glass made by Sir William Crookes for "goggles" to prevent blindness, which transmits the greatest amount of light and the smallest proportion of ultra-violet rays, effectively combats the source of irritation. But the luminous rays of the spectrum under certain conditions may also produce pathological effects; in the slighter cases there is recovery, but in some cases the scotoma is permanent. Some thoughtless people found this out to their cost during the recent partial eclipse of the sun.

SOME CONDITIONS AFFECTING THYROID ACTIVITY.

ACCORDING to W. B. Cannon and P. E. Smith, of the Harvard Medical School,[1] gentle massage of the thyroid of a cat for two or three minutes causes an increased rate of the denervated heart, amounting in some instances to 33 per cent. over the basal rate. The development of the maximal increase of rate is usually slow, requiring 30 to 60 minutes, and its diminution is also slow. This augmentation of heart-rate caused by thyroid massage occurs in the absence of the adrenal glands. Stimulation of the cervical sympathetic trunk as it leaves the ganglion stellatum induces a similar augmentation of the denervated heart, but this does not occur if the thyroid gland has been previously removed. If the cardiac fibres from the stellate ganglia are severed, as well as the vagus nerves and an afferent nerve, such as the sciatic or brachial, is stimulated under a degree of anæsthesia which will permit of reflex contraction of the nictitating membrane and dilatation of the pupils, there is a primary increase of rate due to adrenal secretion.

---

[1] Endocrinology, iv., 1920.

followed by the slowly developing increase characteristic of thyroid stimulation. If the vagi and the cardiac fibres of the stellate ganglia are cut, and the animal is asphyxiated under conditions which permit the eye changes already described, there is a similar primary rise due to adrenal secretion, followed by the secondary thyroid effect. If the thyroid glands have been previously removed, sensory stimulation and asphyxia induce only the increase of rate due to adrenal discharge.

Some interesting observations on hyperplasia and hypersecretion of the thyroid glands in children and adolescents are recorded by E. Schlesinger.[2] In goitrous regions the thyroid is larger in new-born children than in non-goitrous districts. This hypertrophy, however, disappears in a few months, and the follicles of such children later on are smaller in diameter (100–150μ) than normal (200–250μ). In boys there begins at about the ninth and in girls at the sixth–seventh year a new enlargement of the thyroid gland, which diminishes just before puberty. The hyperplasia which occurs in about one-third of the girls and in one-sixth of the boys from 10–17 years of age is accompanied by tachycardia, which in the majority of the cases is not neuropathic in origin, but is a sign of hyperthyroidism. Exophthalmos and thyroid heart were only occasionally observed. An interesting feature was the mental activity and quick comprehension in these cases of thyroid hyperplasia. Growth was accelerated, and in girls the sexual development more pronounced than in the other girls of the same age. Sometimes curvature of the spine and marked myopia were observed. The use of thyreoidin proved very useful and caused the cardio-vascular symptoms to disappear.

THE Croonian Lectures to the Royal College of Physicians of London will be delivered by Dr. F. L. Golla on June 9th, 14th, 16th, and 21st, at 5 P.M. The subject will be the Objective Study of Neurosis.

---

URBAN VITAL STATISTICS.

(Week ended May 7th, 1921.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate population estimated at 18½ million persons, the annual rate of mortality, which had been 12·5 in each of the four preceding weeks, fell to 12·4 per 1000. In London, with a population of 4½ million persons, the annual rate was 11·5, or 0·6 per 1000 below that recorded in the previous week, while among the remaining towns the rates ranged from 6·0 in Enfield, 6·8 in Ealing, and 6·9 in Gillingham, to 19·2 in Halifax, 19·3 in Liverpool, and 19·8 in Stockton-on-Tees. The principal epidemic diseases caused 238 deaths, which corresponded to an annual rate of 0·7 per 1000, and comprised 76 from whooping-cough, 57 from infantile diarrhœa, 55 from diphtheria, 31 from measles, 16 from scarlet fever, and 3 from enteric fever. Whooping-cough caused a mortality of 1·6 in Derby and diphtheria of 2·4 in Acton. There were 3195 cases of scarlet fever, 2343 of diphtheria, and 1 of small-pox under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 3255, 2453, and 1 respectively at the end of the previous week. During the week ended April 30th 4 cases of encephalitis lethargica were notified in the County of London, from Bethnal Green, Camberwell, St. Marylebone, and Woolwich respectively. The causes of 31 of the 4427 deaths in the 96 towns were uncertified, of which 10 were registered in Birmingham.

Scottish Towns.—In the 16 largest Scottish towns, with an aggregate population estimated at nearly 2½ million persons, the annual rate of mortality, which had been 14·6, 14·6, and 15·0 in the three preceding weeks, fell to 14·7 per 1000. The 343 deaths in Glasgow corresponded to an annual rate of 16·3 per 1000, and included 29 from whooping-cough, 6 from infantile diarrhœa, 3 from diphtheria, and 1 from measles. The 124 deaths in Edinburgh were equal to a rate of 14·5 per 1000, and included 5 from whooping-cough and 4 each from measles and diphtheria.

Irish Towns.—The 152 deaths in Dublin corresponded to an annual rate of 18·7, or 1·3 per 1000 above that recorded in the previous week, and included 3 from diphtheria, 2 from infantile diarrhœa, and 1 from whooping-cough. The 125 deaths in Belfast were equal to a rate of 15·5 per 1000, and included 9 from whooping-cough, 3 from infantile diarrhœa, and 2 from scarlet fever.

TUBERCULOSIS.

Results of Proper Sanatorium Treatment.

THE twenty-fourth annual report of the Loomis Sanatorium, New York, must be rather disconcerting to the arm-chair pessimist. This 95-page report is so full of information that it is possible not only to learn the results achieved, but also—and this is far more important—to learn something of the ways and means yielding these results. The Loomis Sanatorium has a capacity for 183 patients "presenting a fair prospect of recovery." In practice this standard means that about 10 per cent. of the cases are incipient, 50 per cent. are moderately advanced, and 40 per cent. are far advanced on admission. To judge by the list of occupations of the patients, they belonged for the most part to the class for which King Edward VII. Sanatorium, Midhurst, caters. After nearly a quarter of a century's work, inquiries were addressed to 1582 former patients. In 1350 cases information as to the fate of these patients was obtained. In 91 per cent. of these replies it was stated that the patient was still alive, and of the 1225 survivors 85 per cent. were "leading normal lives, and, in most instances, pursuing their vocations."

So much for the results. How were they obtained, and why are they so much better than the results obtained elsewhere? The average duration of treatment was from 30 to 45 weeks. How many public sanatoriums in this country keep their patients so long? A resident, fully qualified dentist was employed, and during the past year radiographic dental studies were part of the routine examination of every new patient. "It seems unquestionable that even unrecognised dental disease exerts an unfavourable influence upon the recovery of tuberculous patients." How many public sanatoriums in this country provide their patients with adequate dental treatment? The resident medical staff of the Loomis Sanatorium consists of five. How does this ratio of five doctors to 183 patients compare with the staffing of public sanatoriums in this country? Constantly increasing use has been made of the X rays, not only in diagnosis, but also in controlling treatment. Of serial stereograms the report says: "Such studies will often enable the clinician immediately to make a readjustment of the patient's regime which checks further retrogression, but which, if delayed until the development of more significant symptoms, may not be availing." A few months ago in this country a medical superintendent, in charge of a sanatorium with more than 100 beds, and carrying out treatment by artificial pneumothorax, was refused an application for an X ray apparatus. Not only is the treatment varied greatly at the Loomis Sanatorium, but there is a widely ramified system of research in the laboratory and at the bedside. In how many public sanatoriums in this country are facilities provided for research or even for checking the researches of others? In 17 per cent. of the cases resident in the sanatorium when the report was issued treatment by artificial pneumothorax was being practised. How many sanatoriums in this country still refuse to give any of their patients the benefit of this treatment? With regard to occupational therapy, the report expresses no doubt as to its benefits to the mind, but it does not attempt to decide how far it is beneficial to the body. The occupational therapy practised at Loomis appears to consist of light, skilled work, such as basketry and typewriting, and the exercise prescribed is graduated walking. Conspicuous by its absence is the unskilled heavy labour of trenching and tree-felling meted out to consumptives in some English sanatoriums. Many other distinctive features of sanatorium treatment, as practised at Loomis, might be noted, but the résumé just given should suffice to show that a high percentage of permanent sanatorium cures is not the result of fortuitous circumstances, but of prolonged and skilled treatment.

King Edward VII. Sanatorium: Fourteenth Annual Report.

This report, which covers the period July, 1919–July, 1920, shows that a considerable amount of research work is being carried out in addition to the ordinary routine of treatment. This is all to the good, and it is almost a truism that patients and physicians alike prosper most in institutions in which research follows hand in hand with routine work. Studies have been undertaken into the relation of Pfeiffer's bacillus to tuberculosis, and among 85 cases investigated 8 were found harbouring this bacillus. But only in one case was there evidence to suggest that it might play an important part in the genesis of the patient's symptoms. Other research concerned the acid-fastness of tubercle bacilli and complement-fixation. A large proportion of the staff was given prophylactic vaccine treatment against influenza, and since this vaccination there have been no further indications of influenzal infection among them. The treatment adopted was that of graduated labour, punctuated by adequate rest. In April, 1920, an up-to-date and thoroughly efficient X ray department was opened, and this has proved useful for artificial pneumothorax treatment, which has now been taken up in this institution. A case is referred to in which the physical signs were confined to one side of the chest, but in which an artificial pneumothorax was not induced because the X rays showed both lungs to be involved.

Light on Mixed Infection in Pulmonary Tuberculosis.

Two recent papers illuminate the problem of mixed infection in pulmonary tuberculosis from a hitherto comparatively obscure quarter. Dr. Arthur L. Bloomfield[1] has studied the mechanism of the bacillus carrier state, with special reference to the Friedländer bacillus. He believes that the survival of important pathogenic organisms in the body may depend on the existence of a focus of diseased tissue in the upper air passages, where these organisms multiply and whence they are discharged to other parts of the body. He attempted to produce artificially a carrier state by frequent reinoculations of a person whose tongue was swabbed with a freshly isolated strain of *B. Friedländer*. Cultures were taken at various intervals for a week, but it was found that within 24 hours of the last inoculation *B. Friedländer* could no longer be found. Of 85 unselected persons, 5·8 per cent. proved to be carriers of *B. Friedländer*, and this carrier state persisted throughout the period of observation. But there was no tendency for contacts to acquire the carrier state, and differential cultures showed the breeding-place of the *B. Friedländer* to be in the tonsil. The carrier's own strain or a foreign strain of *B. Friedländer* implanted upon the free surfaces of the mucous membranes disappeared as quickly as in a non-carrier.

The second paper is by E. Schulz,[2] who records, at considerable length, the case of an officer, aged 40, who had suffered from pulmonary tuberculosis since 1908. The most instructive features of his chequered career were these: his sputum contained numerous staphylococci and influenza bacilli as well as tubercle bacilli. The tonsils were not enlarged and gave rise to no symptoms, but their bacteriological examination revealed numerous staphylococci as well as diplococci, Friedländer's pneumococci, and a few granular rods. He was subject to acute exacerbations of fever, which were not permanently controlled by antiseptic treatment of the tonsils. The last bacteriological examination of the tonsils showing an almost pure culture of staphylococci and diplococci pneumococci being conspicuous by their absence, tonsillectomy was performed. Soon afterwards examination of the sputum revealed total absence of cocci, tubercle bacilli alone being found in great quantities. The operation was followed by the disappearance of clinical signs of mixed infection, the temperature being normal, and the sputum sterile except for tubercle bacilli.

In 1913 Brauer drew attention to the relation of "exercise fever" in pulmonary tuberculosis to slight chronic inflammatory changes in the upper respiratory passages, and he focussed attention on the tonsils. More recently John[3] has pointed out that in some cases suspected of pulmonary tuberculosis treatment of the tonsils restores the patient to complete health. Still more recently Kraus[4] has discussed the relation of apical catarrh of the lungs to chronic tonsillitis.

The Framingham Tuberculosis Demonstration.

It may be remembered from earlier accounts[5] that Framingham, Massachusetts, a representative community of approximately 16,000 souls, was chosen as the subject for a gigantic experiment in hygiene, with tuberculosis as the central problem. This demonstration began early in 1917, and was financed by a special gift from the Metropolitan Life Insurance Company to the National Tuberculosis Association. In a recent report Dr. D. B. Armstrong[6] has given a bird's-eye view of the results already achieved. They are, indeed, imposing. His review may be discussed under the following headings:—

Incidence.—Approximately 1 per cent. of the population was found to suffer from active tuberculosis, and another 1 per cent. from inactive tuberculosis. When the search for tuberculosis was started there were only 27 known cases of tuberculosis under care, and there had never been more than 40 known cases at one time, the ratio of known cases to annual deaths being about three to one. An intensive search soon revealed several hundred cases, and the ratio of known active cases to annual deaths was found to be nine or ten to one. As Dr. Armstrong very pertinently remarks, this first step—i.e., discovery of the disease—is essential, for it is of relatively little use to provide adequate machinery for the care of one-third of the active cases in a community if the other two-thirds are undetected.

Machinery for detection of tuberculosis.—Before the demonstration was instituted the detection of tuberculosis largely depended on nurses and other non-medical persons. The examination by medical men disclosed approximately nine times as much tuberculosis as was found by the nurses in their search for the disease. Consequently, though no reflection is cast on the utility of the nurse in the anti-tuberculosis campaign, it is now admitted that the full quota of tuberculosis cannot be found *without proper medical* examination. The routine medical examination of three-fourths of the population of Framingham yielded many discoveries of tuberculosis.

Percentage of cases to be diagnosed at an early stage.—Before the demonstration only 45 per cent. of all the cases were detected at an early stage. Since the beginning of the demonstration this ratio has been raised to 83 per cent. The calculation is made that the remaining 17 *per cent., found* to be advanced when first detected, could be further reduced by 3 per cent., but that at least 14 per cent. of all cases will escape early detection however effective the machinery for early diagnosis may be.

The proportion of inevitable deaths.—To the question, How many patients will die in spite of adequate treatment? the answer is given that, in spite of all measures, the irreducible mortality is probably about 16 *per cent.* This estimate is based on the fact that 21 per cent. of the 356 early and late cases under observation during the four years of the demonstration had terminated fatally. A careful study of these cases suggested that, *with proper machinery*, 5 per cent. could have been saved, and by the subtraction of this 5 per cent. the irreducible minimum of the 16 per cent. mortality is obtained.

Number of beds necessary for the treatment of tuberculosis.—At least one bed should be provided for every annual death.

Cost of a tuberculosis campaign.—Dr. Armstrong finds that it is impossible to separate the cost of tuberculosis work from that of general health work, as the two are closely interwoven. At the beginning of the demonstration Framingham was spending approximately 40 cents per year per head on all kinds of health work. *It is now spending* about $2 per year per head from public and private funds. He proceeds: "This amount of money will buy reasonably adequate pre-natal, infant, and pre-school work; satisfactory school health work; *industrial* health work; special tuberculosis work along many lines; and general community sanitation."

Results.—Tuberculosis as a cause of illness in Framingham is apparently being brought under control. The mortality per 100,000 for the decade preceding the demonstration was 121·5. The corresponding ratio for the period of the demonstration was 84·2—i.e., a reduction of about one-third. For 1920 the corresponding ratio was 64·5 per 100,000—i.e., a reduction of about one-half of the pre-demonstration rate. Should the U.S.A. as a whole follow Framingham's lead, it is estimated that 75,000 lives could be saved annually.

Norfolk Tuberculosis Farm Colony.

The inauguration of this colony was due to the initiative of the Norfolk Branch of the British Red Cross Society, who in 1919 offered to contribute the sum of £25,000 towards the establishment and equipment of a farm colony for patients in whom tuberculosis had been arrested by sanatorium treatment. The offer was conditional on the maintenance and further development of the project being undertaken by the Norfolk County Council, the Norwich City Council, and the Yarmouth Borough Council, who accepted the offer and obtained from the Ministry of Health the appointment of a Statutory Joint Committee to manage the undertaking. A property of over 700 acres was purchased, with good farm buildings, at Stanninghall, five miles from Norwich. The site of the colony is in a very open situation, on high ground, close to the picturesque ruins of an ancient abbey. Existing farm buildings have been utilised as an administrative block, containing committee-rooms and offices and apartments for a resident superintendent, matron, and nurse. There are also good kitchens and a dining-room for the patients. The colony was opened in April, 1920. There are at present 30 inmates, all men. The first patients were housed in a small number of shelters, but a large army hut was purchased later and divided into cubicles for 20 men. These cubicles are open to the south, and each accommodates two patients; they can be closed by curtains when the weather conditions do not admit of their being left open. Another large hut is now being adapted for the reception of 20 more patients. There is a well-equipped carpenter's shop on the premises, built by the inmates, and the men are being trained in carpentering, also in poultry and pig-keeping, making their own fowl-houses and pig-styes, as well as in market gardening, fruit farming, and forestry, under the supervision of experts who give their services voluntarily. A bowling-green is now being laid down, and a large hut has been fitted up as a recreation-room open after 6 P.M. for billiards and other amusements. The colony is under the medical supervision of Dr. W. B. Christopherson, tuberculosis officer for Norfolk, Dr. F. W. Burton-Fanning acting as medical adviser. Mr. H. R. Orr, formerly games master at Elston school, is resident superintendent, and the matron is Miss Bobby, for many years at Kelling Sanatorium. In regard to admissions, preference is given to ex-Service men, who are examined prior to admission in order to exclude acute cases. Beds are allotted in the proportion of three-eighths for Norfolk, three-eighths for Norwich, and two-eighths for Yarmouth. Up to the present the Insurance Committees pay £2 11*s.* for each inmate, but financial support now passes into the hands of the county council. The farm is being carried on as a separate undertaking under the management of Mr. Charles Gowing. The Red Cross Society spent over £9000 on stocking the farm, and it is hoped that as the colony grows the inmates will be able to take over from the farm such land as they can work. In the meantime the farm pays rent to the Joint Committee. The immediate need of the colony is the provision of cottages where married men can have their wives and families to live with them.

DONATIONS AND BEQUESTS.—By the will of the late Mr. Henry John Milbourne the testator left £5000 to Dr. Barnardo's Homes, and £200 each to Middlesex Hospital, King's College Hospital, Guy's Hospital, University College Hospital, East London Hospital for Children, Surgical Aid Society, Great Northern Hospital, and St. Mary's Hospital.—Subject to his wife's life interest, the late Mr. E. A. Eades, of Birmingham, has left, among other bequests, £1250 each to the Women's Hospital, Birmingham, and the Children's Hospital, Birmingham.

MEDICINE AND THE LAW.

What Constitutes "Breach of Agreement" by a Panel Doctor.

REPORTS of Inquiries and Appeals under the National Health Insurance (Medical Benefit) Regulations (England), 1913, which are published from time to time, contains a large amount of information which is of considerable interest to the panel doctor. The first volume, which was published in August, 1917 (Cd. 8549), includes notes of inquiries held upon medical practitioners and persons supplying drugs, reports of appeals against deductions on the ground of excessive prescribing, and of cases relating to questions of "competence and skill." A second volume, published in January, 1919 (Cd. 18), contains reported decisions down to June, 1918. All these reports are anonymous in the sense that the name of the practitioner whose conduct is called in question is not published. Under Section 15 (2) (*b*) of the National Insurance Act, 1911, any duly qualified medical practitioner who is desirous of being included in the medical list of an Insurance Committee is entitled to be so included, but, "where the Insurance Commissioners, after such inquiry as may be prescribed, are satisfied that his continuance in the list would be prejudicial to the efficiency of the medical service of the insured they may remove his name from the list."

The form of the inquiry is prescribed in Part VI. of the National Health Insurance (Medical Benefit) Regulations (England), 1913. These Regulations provide that if any representation is made by an Insurance, Local Medical, or Panel Committee to the effect that the continuance of a practitioner upon the panel is prejudicial to the efficiency of the medical service of the insured, the Commissioners shall thereupon institute an inquiry. If similar representations are made by any other person or body the Commissioners have a discretionary power to institute an inquiry, and they have a further power to do so, in cases where they think fit, in the absence of any representation. For the purpose of each inquiry the Commissioners constitute an Inquiry Committee consisting of three persons, one of whom must be a barrister-at-law or a solicitor in actual practice and the other two medical practitioners. It is the duty of the Inquiry Committee to draw up a report stating such relevant facts as appear to them to be established by evidence and the inferences which may properly be drawn. After consideration of this report the Commissioners take such action, if any, as they think fit. It should be mentioned that it was decided in one case (September, 1917, vol. ii., p. 21) that evidence on affidavit will not be received. A witness must attend and submit to cross-examination. Parties may be represented by solicitor or counsel. By the National Health Insurance Act, 1918, the provisions of the Arbitration Act, 1889, have been applied to these inquiries. The effect of this is that witnesses may be compelled to attend, and costs may be awarded to the unsuccessful party.

It will be useful to deal with some of the cases in which practitioners have appealed to the Commissioners on questions relating to alleged negligence or breach of agreement. Article 45 (16) of the National Health Insurance (Medical Benefit) Regulations (England), 1913, requires an Insurance Committee to inform a medical practitioner of the decision arrived at on any case dealt with by the Medical Service Subcommittee to which he has been a party, and entitles the practitioner to appeal from the decision to the Insurance Commissioners within 14 days after receiving such notice. Article 51 of the same Regulations deals with the procedure on appeal, and empowers the Commissioners either to decide the case without a hearing or, if they think that a hearing is required, to authorise any two or more of their number to hear and determine the appeal. It is important to notice that the Insurance Committee is bound by the agreement with the practitioner, and has no power to go outside it. Thus an Insurance Committee's power to withhold money from a doctor on the panel must be exercised strictly in accordance with the terms of the agreement and regulations conferring the power, which require that the case shall first be investigated by the Medical Service Subcommittee or Joint Services Subcommittee. So a decision to withhold money from a doctor, at which the Committee purported to arrive after the matter had been considered by the Medical Benefit Subcommittee only and without notice being given to the doctor, was held to be invalid.

Again, a charge must be strictly proved by proper evidence. For example, where there was a complaint made by an insured person against a practitioner on the ground that he had failed to attend her, the question turned on the nature of a verbal message alleged to have been sent to the practitioner and of his reply to the messenger. Neither the complainant nor the messenger attended before the Medical Service Subcommittee, nor was any written statement by the messenger put in evidence. It was held that there was not sufficient evidence before the Committee to support the complainant's case.

If a panel doctor appoints a deputy the effect of Clause 8 of the common form of agreement is that the practitioner is responsible in all respects for the acts and omissions of the deputy. The Commissioners have thus interpreted the clause:—

> "This clause does more than impose an obligation on the practitioner to supply a competent deputy. It requires the practitioner, when he is prevented from giving attendance personally, to provide that another practitioner will attend his patients as his deputy on his behalf; and we cannot doubt that in these circumstances the deputy attends the patient as the agent of the other practitioner, who is responsible in all respects for the acts and omissions of the deputy."

In the case, however, of any complaints being made against a practitioner acting as deputy for a practitioner on the panel, the Commissioners have said that notice of the charge and hearing should be sent to both practitioners concerned.

The panel doctor is under a statutory duty to the panel patient. It has been held that a practitioner on the panel and an insured person on his list cannot, by mutual arrangement and without reference to the Insurance Committee, release the former from the obligation to treat the latter imposed by Clause 2 (ii.) of the agreement. Unless and until the insured person is transferred from the doctor's list in accordance with one of the methods provided by the medical benefit regulations the doctor's obligations remain unchanged, and the acceptance of a fee in respect of services within the scope of the agreement involves a breach of the agreement. In the course of a decision the Commissioners made the following observations of a general nature:—

> "It is obvious that it is within the power of a doctor on the panel to adopt an attitude towards his panel patients which will inspire them with misgivings as to the efficacy of the treatment and drugs provided under the panel system. Apart from open disparagement of the system, a feeling of distrust may be created in the minds of his patients, and in particular those who, for whatever reasons, are predisposed to view with suspicion the arrangements made for medical benefit. If it comes to the notice of an Insurance Committee that in more than one instance the patients of a panel doctor have expressed their intention of foregoing their right to medical benefit and of obtaining treatment from the *same* doctor as private patients, the conduct of the doctor is clearly liable to misconstruction."

The Commissioners pointed out that there was nothing in the case before them to lead them to suppose that the practitioner whose conduct was under notice had erred in this respect.

A marked distinction is drawn by the Commissioners between mere error of judgment and negligence. In one case the appellant, who had treated a patient for neurosis, chronic rheumatism, and biliousness from September, 1913, to Jan. 31st, 1914, visited the patient in response to a message from the latter's wife on Feb. 1st, 1914, and examined him without taking his temperature. In the afternoon the patient called in another practitioner who diagnosed rheumatic fever. The Insurance Committee found that the allegation of neglect on the part of the appellant had been substantiated. It was held that, while the failure of the appellant to take the patient's temperature might have been an error of judgment, it did not constitute a breach of his agreement. In another case the Medical Service Subcommittee held that a charge of one guinea for attending a consultation was not justified. The practitioner appealed. It appeared that the appellant while attending a patient for typhoid fever was asked by the patient's mother, who was acting as his nurse, to meet another practitioner in consultation. The appellant consented to do so, but charged a fee on the ground that the consultation was unnecessary and that in attending it he was acting on behalf of the patient's mother. On a complaint by the insured person, the Insurance Committee decided that the charge was a breach of the appellant's agreement. It was held that as the appellant had in fact attended the consultation his action was for the general benefit of the patient, and in view of the mother's anxiety the consultation was not unnecessary. In giving their decision the Commissioners pointed out that it was open to the practitioner to refuse to attend the consultation if he believed that no benefit to his patient would result therefrom, directly or indirectly.

The procedure to be adopted by a practitioner who declines to accept a particular patient is laid down in the regulations. Arrangements made under Article 21 (4) of the Medical Benefit Regulations, 1913, required an insurance practitioner, who refused to accept an insured person for treatment, to give him a form containing instructions as to the steps to be taken to obtain treatment. In one case appellant, to whom an insured person applied for treatment, having refused treatment under the medical benefit arrangements and omitted to give the patient the form referred to, accepted the insured person as a private patient and subsequently charged him £5. It was held that the practitioner had committed a breach of his agreement with the Insurance Committee. It was also decided in this case that the fact that the doctor might, if he had put in motion the proper procedure, have had it established that some of the services rendered by him to the patient were of a specialist character, and therefore outside the scope of his agreement, did not justify his action.

In issuing certificates of "incapacity" the practitioner cannot divest himself of his responsibility by calling in a medical referee. In one case an insurance practitioner, being doubtful as to the continued incapacity for work of an insured person attended by him, suggested to the patient's Approved Society that an examination by a medical referee was advisable. The referee having stated that in his opinion incapacity still existed, the practitioner continued, notwithstanding his personal opinion to the contrary, to issue certificates of incapacity, some of which were given without examining the patient. It was held that the practitioner could not evade his personal responsibility for the issue of medical certificates by pleading that he acted on the opinion of a medical referee. His proper course was to have refused to issue certificates.

In one case the appellant, while attending an insured person on his list who was seriously ill, stated in the presence of her mother and herself that she required a drug which was very expensive and which he could not order owing to her being on the panel. In consequence of this statement the patient's mother engaged another doctor and paid for his services. It was held that the doctor's action was not consistent with the professional obligations which he had undertaken by the terms of his agreement with the Insurance Committee, and that the expense of employing another doctor was reasonably incurred in consequence of the appellant's breach of the agreement. The referee in giving his opinion said:—

> "The appellant on the occasion in question made use, without justification, of language which gave his patient and her mother reasonable ground for believing that the patient could not receive adequate treatment as an insured person, and that such action is not consistent with the professional obligations which the doctor by the terms of his agreement had undertaken to discharge."

The doctor should not make any attempt to disparage the panel system or panel treatment.

Arsenic in Borax.

A summons under the Sale of Food and Drugs Act was heard at Salford on April 27th against a pharmacist for selling borax not of the nature or substance demanded. Borax sold to a health inspector contained arsenic equal to 3 gr. per pound of borax, instead of 1/28 gr., as required by the British Pharmacopœia. The defence relied on a warranty obtained from the supplying firm. The pharmacist ordered B.P. borax, but apparently received a bag of commercial borax intended for another customer. The stipendiary upheld the view that the defendant had a warranty within the meaning of the Act and dismissed the summons. In another case the sample of borax contained arsenic equal to $1\frac{1}{2}$ gr. per pound of borax. In neither case was it suggested that the defendants had caused the adulteration. The defendant bought borax from two firms, but did not know from which he received the consignment from which the inepector's sample was taken. He always ordered B.P. borax. No question of warranty was raised. The Stipendiary in this case said there was 42 times more arsenic in the sample than there should be. A fine of one guinea was imposed.

It will be noted that in both the above cases the defence was that of "warranty," the defendant being entitled to have the charge dismissed on proving that he "purchased the article in question as the same in nature, substance, and quality as that demanded of him by the prosecutor, and with a written warranty to that effect"; also that he had no reason to believe it to be otherwise, and that he sold it in the same state as when he purchased it. A very large number of cases have turned upon the question as to what constitutes a written warranty within the above section (§ 25 of the Food and Drugs Act, 1875). Invoices have been rejected as such in the past when not quite distinct in their terms. But an invoice stating that the sale was one of B.P. borax was presumably deemed sufficient in the first of the above examples, and in the second it is clear that a defendant, who could not say on oath from which of two consignments from different firms he had taken the sample sold, could not connect with it anything in the nature of a written warranty. For his own protection, as well as for that of the public, a druggist should insist on his wholesale supplier warranting distinctly on his invoices the nature and quality of the goods that he delivers. It is to the public interest that strict proof of a warranty should be insisted upon.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Syndicates of Medical Men.

SINCE you have recently discussed in your columns the ethics and the practicability of some form of combined action on the part of medical men or allied professions, the position in France may be of interest to your readers. There are several syndicates of medical practitioners in France. Their members are practitioners who live in the same district. These syndicates are nearly all grouped in a union: "Union des Syndicats Médicaux de France," the members of which are chiefly general practitioners. Few consultants have so far joined the existing syndicates and there is no independent syndicate of consultants. A syndicate of hospital attendants (orderlies) as well as a syndicate of nurses had originally been set up by those employed in State hospitals; these syndicates later amalgamated in one under the heading: "Syndicat Général du Personnel des Hôpitaux, Hospices et Maisons de Santé de l'Assistance Publique." This syndicate and similar ones in the French Provinces and colonies are grouped in a federation: "Fédération des Services de Santé de France et des Colonies." One of these syndicates is even now fighting a battle against the State on behalf of its members. As reported in a previous letter the decision of the Ministry of Pensions concerning the remuneration of practitioners treating pensioners has been opposed by the Union des Syndicats Médicaux de France, who have decided not to consider the decree of the Ministry of Pensions. The committee of the Syndicat Médical de Paris have urged its members to uphold the decision arrived at by the Union des Syndicats Médicaux de France, and more especially to refuse to fill in and sign forms issued by the Ministry of Pensions. Members of syndicates were asked by the committee to continue to give medical attendance to pensioners, but to treat them as ordinary patients. It has now been proposed by the Union Fédérale des Associations des Mutilés et Réformés de Guerre to refer the decision to a committee consisting of delegates from the Ministry of Pensions, the Associations of Pensioners, and the Medical Syndicates.

Analysis of Water in War Zone.

At a recent meeting of the Société de Médecine Publique et de Génie Sanitaire Mr. R. Wibaux submitted a report on the present organisation of the laboratories exclusively devoted to analysis of waters in the French counties which were invaded during the war. They were set up for this special purpose soon after the war by the Ministère des Régions Libérées. In his report Mr. Wibaux pointed out that originally laboratory lorries were used, but were ultimately replaced by laboratories installed temporarily on any available premises. A motor-car is attached to each temporary laboratory, and it is the duty of a bacteriologist to drive to the various wells in the district to procure the specimens of water to be tested. Mr. Wibaux expressed the wish that such services should remain permanent, and that they should be extended to the whole of the country on a large scale.

Reorganisation of Sanitary Services.

It has been proposed to revise the Medical Act of Feb. 15th, 1902, which deals with the organisation of the sanitary services in France. The French Government has been seeking the opinion of the members of the Académie de Médecine on this matter, and they have been officially asked to express their views. A special committee has been appointed to that effect, and the last meetings of the Academy of Medicine have been largely devoted to debates on the committee's report. In the course of one of these meetings Mr. Léon Bernard emphasised the opinion that sanitary conditions in any area should not be regulated by the local authorities, but should be under the immediate control of a chief medical officer of health, who would superintend an extensive area.

Franco-Anglo-American League against Cancer.

The annual meeting of the Franco-Anglo-American League against Cancer was held at the Faculté de Médecine de Paris on April 19th, Mr. Lerédu, Minister of Hygiene, in the chair. At the opening of the meeting Professor H. Hartmann expressed a vote of thanks to those who had given grants to the League. A report of the managing committee was read by Mr. R. Le Bret, general secretary. Mr. J. Worth, the treasurer, submitted a financial report. Professor C. Regaud suggested that great benefit to the population might ensue if pamphlets were distributed under the joint auspices of the League, the Academy of Medicine, and the Pasteur Institute, pointing out the necessity of early surgical treatment of cancer.

War Memorial for Internes Killed in the War.

A war memorial was unveiled a few days ago at the Hôpital de l'Hôtel-Dieu in memory of the internes who were killed in action. Speeches were made by Mr. Bérard, Minister of Education; Mr. P. Mourier, Director of the Administration de l'Assistance Publique; Mr. H. Roger, Dean of the Faculté de Médecine de Paris; and General Buat, representing the Minister of War. The President of the Republic, the President of the Senate, the Minister of Hygiene, Marshal Foch, Marshal Petain, and the Rector of the Academy were also represented at the ceremony.

May 11th.

A MONTHLY RECORD OF ATMOSPHERIC POLLUTION.

METEOROLOGICAL OFFICE: ADVISORY COMMITTEE ON ATMOSPHERIC POLLUTION: SUMMARY OF REPORTS FOR AUGUST, SEPTEMBER, OCTOBER, NOVEMBER, 1920.

August.

Place.	Rainfall in millimetres.	Metric tons of deposit per square kilometre.

Ti. = Total insoluble. Ts. = Total soluble. Tr. = trace. * East side of town. † West side of town. ‡ Town.

"Tar" includes all matter insoluble in water but soluble in CS_2. "Carbonaceous" includes all combustible matter insoluble in water and in CS_2. "Insoluble ash" includes all earthy matter, fuel, ash, &c. One metric ton per sq. kilometre is equivalent to: (a) Approx. 9lb. per acre; (b) 2·56 English tons per sq. mile; (c) 1 g. per sq. metre; (d) 1·000 mm. of rainfall.

The personnel of public health authorities concerned in the supervision of these examinations and of the analytical work involved remains the same as published in previous tables. The analyses of the rain and deposit caught in the gauge at the Meteorological O were made in THE LANCET Laboratory.

Correspondence.

"Audi alteram partem."

EARLY DIAGNOSIS IN DIPHTHERIA.

To the Editor of The Lancet.

Sir,—For the past two years it has been impressed upon me that sufferers from diphtheria have been arriving at my hospital, on the whole, rather later in the disease than was the case for a good many years previously. The death-rate in 1919 was 13·6 per cent., and I have to go back to 1901 to find a death-rate either exceeding or equalling it. In 1920 the death-rate was 11·2, and I have to go back to 1903 to find that exceeded or equalled. Certainly the death-rates of 1919 and 1920 were higher than one would have expected, and naturally one looks for some explanation. A simple one would be that the disease was more severe in type, but though I am not prepared to deny that the type may have been somewhat more severe I am satisfied it was not the main cause, if, indeed, it affected it at all materially. The real explanation appears to be what I have just called attention to—the fact of so many patients arriving at the hospital after the disease was well advanced and without previous antitoxin treatment.

This slower recognition of diphtheria of late has puzzled my mind, and I have striven to find the explanation, but evidently no one reason by itself gives a satisfactory explanation. It is not to be assumed that only the milder forms come in late; it is any kind of diphtheria, and quite commonly the most severe. This cannot all be laid at the door of the practitioner, for it is quite clear that on many occasions he is not called in at the commencement of the disease, but for what proportion this accounts he would naturally be a better judge than I. There can be no doubt, however, that delay is greatly attributable to awaiting the result of a bacteriological examination. At first sight it seems curious that this should have increased, but it may be that so many practitioners were not in civil practice during the war, and consequently had not the opportunity to study diphtheria clinically.

Yet I do not think that is the sole cause of the tendency to wait for bacteriological examination, for some scientific books lay too much stress on the finding of the bacillus, and I have even been told by a medical man that the medical officer of health expected it. I do not know how far the medical officer of health may be considered responsible, but an excellent scientific text-book states that examination of the membranous exudation with the demonstration of the presence of the diphtheria bacillus is the only reliable method of diagnosis. This kind of erroneous statement might best be met by the epigrammatic remark of an authority on diphtheria: "Were it not that the diphtheria bacillus had given us antitoxin, it would have been well had it never been discovered." I have no wish to discourage bacteriological examination; indeed, I always carry it out, but to let treatment wait upon the result of the examination means delay, and delay in diphtheria often means death. For 15 years MacCombie kept records of the diphtheria death-rates according to the day on which the disease was treated with antitoxin, and as these results were founded on over 7000 cases they may be taken as conclusive. The death-rate when antitoxin was given on the first day was 0·5 per cent.; on the second day 4 per cent.; on the third day 10 per cent.; on the fourth day 15 per cent.; and on the fifth and succeeding days 16 per cent.

My own experience of treatment on the first day has not been quite so good as MacCombie's, but his figures demonstrate what waiting without treatment for a bacteriological examination means. Moreover, it must be remembered that the bacteriologist, at all events at first, may fail to find the bacillus in well-marked diphtheria, and maybe another swab is taken with further delay. As a matter of fact, failure to find the bacillus in a culture taken early in the disease is not uncommon. It may not be found even in a second or third culture, and rarely not at all. Failure to find the bacillus in purely laryngeal diphtheria is common and well known, but perhaps it is not so well known that in the severest form of faucial diphtheria cultures taken on the first day are not uncommonly negative. On the other hand, the case for examination may be a carrier and the finding of the bacillus of no value. Nevertheless, a culture should always be taken, and care should be exercised in the choice of examiner, the dabbler in bacteriology being avoided.

However, in milder forms of faucial disease with a suspicion of diphtheria, sometimes the question will arise whether one ought to let treatment wait for the culture result. The difficulty is often great, for the point one has to decide in such a case is whether the disease will continue mild or develop into a severe attack. In my experience this is difficult to do without occasional error, and I think there can be no doubt that if the clinical evidence favours diphtheria the patient should be treated for that disease at once. In practice it comes to this: if one is sufficiently experienced to say that a given patient will certainly recover if treatment is postponed to the second or third day, then one may wait, but if one cannot say so then it is one's duty to give antitoxin.—I am, Sir, yours faithfully,

Frederic Thomson.

North-Eastern Hospital, Tottenham, N., May 12th, 1921.

THE INTERNECINE VENEREAL CAMPAIGN.

To the Editor of The Lancet.

Sir,—Lord Gorell states in his letter which you printed in your issue of May 7th that there is now admitted to be but one point of difference between the two societies. In order that your readers may appreciate the extent of the difference it is necessary for them to read our letter to Lord Gorell of April 22nd, which was not published in full in The Lancet. We adhere to the position defined in that letter, and are still ready to meet the National Council for Combating Venereal Diseases according to our letter to the Bishop of Birmingham of Feb. 25th, accepting his invitation to a round table conference, on the understanding that the National Council for Combating Venereal Diseases were prepared to take action forthwith on the terms of the report of the Bishop's committee.

The National Council for Combating Venereal Diseases did not accept this invitation, therefore the conference did not take place.—We are, Sir, yours faithfully,

Willoughby de Broke,
President of the Society for the Prevention of Venereal Disease.
H. Bryan Donkin,
Vice-Chairman. Executive Committee, S.P.V.D.
H. Wansey Bayly,
Honorary Secretary, S.P.V.D.

Harley-street, W., May 13th, 1921.

A LEARNED LAYMAN ON VENEREAL DISEASE.

To the Editor of The Lancet.

Sir,—Many of your readers have read the recent series of articles in the *Morning Post* by Mr. Harold Cox, entitled "The Path to Pauperism." They are written with interest and power, and deservedly arrest attention. The skill which has enabled their author to exercise such influence is to be envied; but, unfortunately, we possess in these articles a striking example of how one, who possesses ability both as a publicist and a literary man, can become by deficient knowledge lacking in accuracy. This is all the more regrettable as the subject of venereal disease is so clearly a public and not only a professional matter.

In the *Morning Post* of April 28th Mr. Cox treats of the Ministry of Health under the three headings of (1) Departmental Rivalries, (2) Venereal Disease, (3) Maternal and Child Welfare; and it is the second of these sections—viz., that dealing with venereal disease

—on which I desire to comment. The problem of venereal disease in relation to the nation's welfare is an extremely complex one, in respect to both its medical and sociological aspects; and Mr. Cox exhibits a degree of knowledge which is superficial, and therefore dangerous, especially in view of the prestige conferred on his statements by his own position and that of the journal in which his words appeared.

Mr. Cox, having previously indicted the Ministry of Health on the charge of being indifferent "to the true interests of the health of the nation," proceeds to level a similar charge against that body with regard to its attitude towards venereal disease. He attracts our attention by stating that syphilis and gonorrhœa are "the most easily preventable of all diseases." He fails, however, to indicate the nature of those preventive measures which so easily secure success. He then considers the attitude of "two private societies." His description of the Society for the Prevention of Venereal Disease is imperfect and substantially fails to do justice to that body. He writes that it "adopts the common-sense view that the prevention of venereal disease is an obligation resting upon the individual and also a matter of immense importance to the nation. It, therefore, demands that facilities should be provided for individuals to obtain the knowledge and the means by which venereal disease can be prevented." The Society for the Prevention of Venereal Disease, in addition to zeal for the adoption of medical measures, also recognises the importance of the ethical and religious factors in the prevention of venereal disease, and Mr. Cox fails as a critic by omitting so important a fact in relation to this Society.

He then proceeds to deal with the National Council for Combating Venereal Diseases, saying:—

> "The other Society takes the view that nothing should be done to help in the prevention of the disease, but that as soon as the disease has been acquired public money should be spent in trying to cure it. The latter Society receives large subsidies provided out of the taxpayers' money to enable it to advertise itself. For this purpose, as Dr. Addison confessed in the House of Commons, the country has had to pay about £13,000 a year for the last three years. How much is to be spent in the current year on advertising this futile Society has not yet been announced, but the total sum asked for by the Ministry of Health and similar bodies in Scotland and Ireland on account of venereal disease is £512,550. None of this money is to be spent on effective methods of prevention. The so-called Ministry of Health prefers that people should first run the risk of getting the disease, and that the Department should then try to cure them. This policy is apparently due to theological as well as departmental considerations. Dr. Addison and his staff seem to have held the view that venereal disease is an affliction designed by Providence as a penalty for sin. Historically that is a curious view, because syphilis, at any rate, did not appear in this country till late in the Middle Ages, and it may be presumed that there was sin before that time. Apart from this historical fact, the Addisonian theory is still difficult to understand. In effect Dr. Addison and his theological and medical advisers have been saying, "Since disease is a punishment for sin, we will not allow people to know how they can prevent it. Nevertheless, we will do our best to cure them at the taxpayers' expense when they have acquired it."

Mr. Cox thus accuses both the Ministry of Health and the N.C.C.V.D. of refusing to take steps in respect to the prevention of venereal disease, while spending public money in attempting to cure those who have fallen victims. He has not thought it worth while to inquire what views are held on this matter by either the Ministry or the National Council. Now both the Ministry and the Council realise that the fundamental cause of venereal disease is the indulgence in promiscuous sexual intercourse, and also that it is their duty to diminish causes rather than treat symptoms. They know that much of the promiscuous sexual intercourse which gives rise to venereal disease is due to the lack of efficient education of the young, of adolescents, and even of adults in sexual matters. They rightly devote, therefore, a substantial portion of their attention towards dissemination of such instruction as will tend to prevent the occurrence of those conditions, which experience has shown to be provocative of promiscuous sexual intercourse, and therefore of venereal disease. The Ministry and the Council are not irrational idealists, nor do they confine their efforts to educational methods. They also advocate efficient cleansing by those who will wilfully or carelessly persist in placing themselves in danger. Mr. Cox's statement as to the N.C.C.V.D. taking the view "that nothing should be done to help in the prevention of the disease" is untrue.

Turning to the financial aspect of the question, Mr. Cox has no idea as to the cost to the country of venereal disease. The sums spent by the adoption of far-seeing and rational methods for reducing the cause of these diseases will prove the means of saving the country a vast expense. The propaganda work carried out by the National Council is of estimable value, for it is directed to the very root of the evil. To regard this money as being spent "in advertising this futile Society" merely because an important branch of their work is carried out through the channels of the press is childish in the extreme. The remarks as to venereal disease being regarded by the N.C.C.V.D. as a punishment for sin, have as far as I can find, no basis, and their humour becomes malicious. Mr. Cox has, I think, trustfully accepted statements concerning the bodies which he abuses without understanding their activities. His articles produced under the ægis of so respected a journal, and signed by so respected a publicist are capable of doing great damage to the nation.

I enclose my card, from which you will see that I ought to know my subject.

I am, Sir, yours faithfully,

May 14th, 1921. A MORPHOLOGIST.

SURGICAL SHOCK.

To the Editor of THE LANCET.

SIR,—In THE LANCET of May 7th a review of "Principles of General Physiology" by Professor W. M. Bayliss mentions the theory that in surgical shock a widespread dilatation of capillaries leads to a pooling of blood. I believe that surgeons who have seen many cases of shock have failed to find pooling of blood in capillaries. Would Professor Bayliss or your reviewer state where, in a human subject suffering from surgical shock, these dilated capillaries are to be found?

I am, Sir, yours faithfully,

Plymouth, May 8th, 1921. C. HAMILTON WHITEFORD.

Professor Bayliss, to whom we referred Mr. Whiteford's inquiry, replies as follows:—

I thank you for giving me the opportunity of making a few remarks on Mr. Whiteford's letter. He does not tell us what evidence of pooling in capillaries surgeons have looked for and failed to obtain. Since the effect in question is not confined to the capillaries of any particular region and the total volume of these vessels, compared with the rest of the vascular system, is enormous, it is clear that a dilatation too small to be detected by direct observation may produce a large increase in the total volume. The evidence, in the nature of things, must be more or less indirect. It would be impossible to give it adequately in a brief account, and those interested may be referred to the special reports of the Medical Research Council, Nos. 25, 26, and 27, especially the two latter. In summary, it may be given thus. Observations during the war on shock unaccompanied by hæmorrhage showed that the low blood pressure was not due to any heart effect, nor to pooling of blood in arteries or veins. But it was found by the vital red method that the blood in actual circulation was greatly reduced. The dilatation of arteries and veins having been ruled out, it could only be in the capillaries. Other confirmatory evidence was obtained and the conclusion was greatly strengthened by the discovery of toxic substances having the required action. In addition to the literature quoted in the reports mentioned, Mr. Quénu's book, "Toxémie Traumatique," deals with this aspect of wound shock.

West Heath-road, N.W., May 12th, 1921.

THE DANGER OF ATHLETICS FOR GIRLS AND WOMEN.

To the Editor of THE LANCET.

SIR,—I have read with great pleasure Miss C. Cowdroy's letter in THE LANCET of May 14th under this title. My experience leads me to agree with her entirely. I have seen a number of girls and young women whose health has been permanently damaged by indulgence in strenuous athletics, and even if they escape physical injury I find they have degenerated into beings of neutral sex who are unfitted for either the work of men or women. Whilst writing on this subject I should like to mention another harmful and dangerous craze. Physical jerks for the middle-aged has done a great deal of harm to many people. The average man or woman of 50 can keep perfectly fit if he or she does not over-eat or drink too much and takes a good amount of walking exercise daily. If they do this there will be no need for "physical jerks." If they do not they may easily "jerk" themselves into their graves.

I am, Sir, yours faithfully,
LESLIE THORNE THORNE, M.D.

Harley-street, W., May 14th, 1921.

INTRAVENOUS INJECTION OF STIBENYL IN KALA-AZAR.

To the Editor of THE LANCET.

SIR,—With reference to the dosage of stibenyl in the treatment of kala-azar and other tropical diseases raised in Dr. P. Manson-Bahr's letter in your issue of May 7th, it ought to be made clear that each batch is tested for toxicity by the Medical Research Council, and all material issued for use conforms with their standard. Stibenyl is tested on mice, as in the case of salvarsan, and the dose that must be tolerated is 0·15 mg. per gramme body-weight used intravenously in a concentration of 1 per cent. The maximum dose that has been suggested for an adult person is 0·6 g., which should allow a very large margin of safety.

We are, Sir, yours faithfully,
ALLEN AND HANBURYS, LTD.

Bethnal Green, London, E., May 12th, 1921.

The Services.

ARMY MEDICAL SERVICE.

Cols. H. N. Dunn (late R.A.M.C.) and H. J. M. Buist retire on retired pay.

ROYAL ARMY MEDICAL CORPS.

Major S. McK. Saunders is restored to the establishment.

Capts. G. K. Maurice and W. Pailthorpe are seconded for service with the Egyptian Army.

Capt. A. W. Bevis retires, receiving a gratuity.

Temp. Capts. T. M. Richardson and V. H. L. MacSwiney relinquish their commissions and retain the rank of Captain.

TERRITORIAL FORCE.

Major J. G. McCutcheon (late R.A.M.C., Special Reserve) to be Captain, and relinquishes the rank of Major.

Captains to be Majors: J. G. McCutcheon, G. E. J. A. Robinson, F. R. M. Heggs, and E. L. D. Dewdney.

Major F. W. Kendle, T.D. resigns his commission and retains the rank of Major with permission to wear the prescribed uniform.

Supernumerary for Service with O.T.C.—Major W. D. Sturrock, from General List, to be Major, and to command the Field Ambulance Section, Oxford University Contingent, Senior Division, O.T.C.

TERRITORIAL FORCE RESERVE.

Capt. A. Coleridge to be Major.

DEFENCE FORCE.

To be temporary Majors: J. M. Cowan and W. Haig. To be temporary Captains: J. M. Chrystie, A. H. D. Smith, R. Morshead, A. G. Williams, A. E. H. Reid, D. C. Graham, and V. T. W. Eagles. To be temporary Lieutenants: E. H. Mayhew, J. E. Sinclare, and A. N. Rushworth.

2nd Highland Field Ambulance (D.F.).—To be temporary Lieutenant-Colonel: J. W. Tocher. To be temporary Major: W. F. T. Haultain. To be temporary Captain: H. J. Rae. To be temporary Lieutenant. H. J. Dawson.

1st London Field Ambulance (D.F.).—O. W. McSheehy (Major, R.A.M.C.) is granted the rank of temporary Lieutenant-Colonel while commanding a Field Ambulance. To be temporary Major: E. Knight. To be temporary Captains: A B. Mount, A. L. Robinson, and R. J. Arundel.

1st London Sanitary Section (D.F.).—To be temporary Captain: H. C. Sands.

2nd London Field Ambulance (D.F.).—To be temporary Lieutenant-Colonel: H. G. Haynes. To be temporary Captains: M. Coughlan and W. Hassard. To be temporary Lieutenant: G. W. Almeyde. To be temporary Quartermaster with the rank of Captain: A. J. H. Knight.

3rd London Field Ambulance (D.F.).—To be temporary Lieutenant-Colonel: M. H. Allen. To be temporary Captain: L. J. G. Carre.

4th London Field Ambulance (D.F.).—To be temporary Captain: C. H. Welch.

5th London Field Ambulance (D.F.).—To be temporary Lieutenants: J. R. K. Flemming and H. W. Collins.

6th London Field Ambulance (D.F.).—To be temporary Captain: E. H. Bingley.

2nd (London) Divisional Sanitary Section (D.F.).—To be temporary Captain; H. Brian-Pearson.

1st (Lowland) Field Ambulance (D.F.).—To be temporary Lieutenant-Colonel: E. S. Forde. To be temporary Major: E. P. Cathcart. To be temporary Captain: J. K. Rennie. To be temporary Lieutenants: A. H. Jacobs and N. M. D. Fox.

2nd (Lowland) Field Ambulance (D.F.).—To be temporary Lieutenant-Colonel: G. B. Fleming. To be temporary Major: J. R. C. Greenlees.

3rd South Midland Field Ambulance (D.F.).—To be temporary Lieutenant-Colonel: T. A. Green. To be temporary Major: D. S. A. O'Keeffe. To be temporary Captains: A. D. Symons and J. C. Brasher. To be temporary Lieutenant: B. A. Astley-Weston.

1st East Anglian Field Ambulance (D.F.).—To be temporary Captains: A. G. Atkinson and H. F. Gilmour.

2nd East Anglian Field Ambulance (D.F.).—To be temporary Captain: W. T. G. Boul.

3rd (Highland) Field Ambulance (D.F.).—To be temporary Lieutenant-Colonel: G. W. Miller. To be temporary Major: W. A. Robertson. To be temporary Captain: J. Kinnear.

1st (Home Counties) Field Ambulance (D.F.).—To be temporary Captain: E. A. Houchin.

2nd (Home Counties) Field Ambulance (D.F.).—To be temporary Captain: R. A. Freeman.

3rd (Home Counties) Field Ambulance (D.F.).—To be temporary Captain: V. E. Negus.

3rd (Welsh) Field Ambulance (D.F.).—To be temporary Lieutenant-Colonel: C. L. Isaac.

1st Wessex Field Ambulance (D.F.).—To be temporary Lieutenant-Colonel: A. Cary. To be temporary Major: R. Ward.

ROYAL AIR FORCE.

T. P. Harpur is granted a temporary commission as Flying Officer.

INDIAN MEDICAL SERVICE.

The King has approved the grant of the rank of Captain to the undermentioned on relinquishing their temporary commissions: Moses Solomon, Jamna Das, Jitendra Kumar Banerji, Ullah Anantthaya, and Ram Chandra. And the honorary rank of Lieutenant-Colonel to the undermentioned on relinquishing his temporary and honorary commission: Raghavendra Row.

The King has approved the retirement of the following officers: Brevet Col. C. M. Goodbody and Lieut.-Col. S. E. Prall.

DEATHS IN THE SERVICES.

Sir Robert William Jackson, C.B., Deputy Surgeon-General, retired, died on May 12th at Dublin in his ninety-fourth year. He entered the Army Medical Department in 1854, served in the Crimea, and was present at the fall of Sevastopol. He served throughout the Indian Mutiny, and was present at the relief of Lucknow and at the Battle of Cawnpore (medal with three clasps). He also took part in the Ashanti war (mentioned in despatches), and saw service in South Africa. In Egypt he was present at the Battle of Tel-el-Kebir (medal with clasp and bronze star). He retired in 1882, in which year he was knighted.

NORTH EUROPEAN CONFERENCE ON VENEREAL DISEASES.—This Conference opens at Copenhagen to-day (May 20th) with an address by Sir David Henderson, Director-General of the League of Red Cross Societies. The following special problems are to be presented: 1. The supply and cost of arsenical compounds for the treatment of syphilis; the possibility of establishing an international standard for the export and import of such compounds. Discussion to be opened by Dr. Kristian Grön for the Norwegian Red Cross Society. 2. The provision in important ports, by international agreement, for the treatment of cases of venereal diseases among sailors, and measures to be taken in connexion therewith. Discussion to be opened by Lieutenant-Colonel L. W. Harrison for the British Red Cross Society. 3. The part of the Red Cross in combating venereal disease, its relation to Government and voluntary agencies. Discussion to be opened by Professor C. E. A. Winslow for the League of Red Cross Societies. 4. Medical measures for the prevention of venereal diseases. Discussion to be opened by Dr. Jersild for the Danish Red Cross Society. The British delegates to the Conference are Colonel Harrison, Dr. F. N. Kaye Menzies, and Mrs. Neville Rolfe. The German Red Cross is represented by Professor J. Jadassohn, Professor Galewsky, and Professor F. Pinkus.

Parliamentary Intelligence.

HOUSE OF LORDS.

WEDNESDAY, MAY 11TH.

Public Health (Tuberculosis) Bill.

THE Public Health (Tuberculosis) Bill was read a third time and passed. (The measure received the Royal Assent on the following day.)

THURSDAY, MAY 12TH.

Criminal Law Amendment Bill.

The Earl of CRAWFORD, replying to the Bishop of London, who asked whether the Government would be able to grant facilities for the passing of the Criminal Law Amendment Bill this session, said that if the measure continued to maintain the non-controversial character with which it left their lordship's House the Government would be glad to do its best at a later stage of the session to pass it into law. No more definite indication than this could be given owing to the fact that there was considerable pressure on the time of the House of Commons.

HOUSE OF COMMONS.

TUESDAY, MAY 10TH.

Rabies in England.

Mr. HUGH MORRISON asked the Minister of Agriculture whether there had been at least 18 cases of rabies in England since January last as against only three cases for the same period in the previous year; whether a dog infected from rabies had been found 70 miles from its home; whether dogs who had developed the disease after being watched were in confinement for seven and a half months; and, if so, was he satisfied that the present regulations were sufficiently stringent to stamp out the disease.—Sir A. GRIFFITH-BOSCAWEN replied: (1) The number of cases of rabies confirmed in Great Britain since Jan. 1st last is 17, but 3 of these refer to dogs which had died in the previous year. The actual number of cases this year is therefore 14 compared with 4 during the corresponding period of last year. (2) Dogs suffering from rabies have been known to wander for 70 miles from their homes, but the longest distance which a mad dog has wandered recently in this country is approximately 50 miles. (3) In one case only in this country in recent outbreaks has the disease taken seven and a half months to develop. The average period of incubation for the series has been two and a half months, and no case has arisen in a dog after its release from quarantine for the prescribed period of six months. The Ministry is satisfied that the existing regulations are adequate.

WEDNESDAY, MAY 11TH.

Orthopædic Hospital at Hammersmith.

Sir WILLIAM BULL asked the Minister of Pensions whether, in view of the difficulty experienced by the Hammersmith board of guardians in finding suitable accommodation for the sick poor of that borough, due to the exclusive occupation of the workhouse and infirmary in Ducane-road by the Ministry of Pensions for use as an orthopædic hospital, and in view of the fact that the full accommodation of this establishment, 800 cases, did not now appear to be required, the greatest number accommodated at any one time since Jan. 1st, 1921, having been 686 cases, he could give a definite assurance that these premises would be restored to the Hammersmith board of guardians on Jan. 1st, 1922, as indicated in conferences which had taken place between representatives of the Ministry and of the local authorities held variously since June, 1918.—Major TRYON (Parliamentary Secretary to the Ministry of Pensions) replied: The matter is under consideration and I am unable to make a definite statement at the present moment. I am communicating with my honourable friend.

Food for Children Under Five.

Mr. TYSON WILSON asked the Minister of Health whether, in view of the widespread distress in the country, he would cancel Circular M. and C. W. 185, issued March 31st, 1921, and re-issue Circular M. and C. W. 4, of August 9th, 1918, so that maternity and child welfare committees might provide children under 5 years of age with food.—Sir ALFRED MOND replied: Circular 185 does not alter the conditions previously prescribed on which food may be supplied to children under 5, except in regard to the supply of milk, which under the Circular is to be supplied free, or at less than cost price, only in necessitous cases. In the circumstances no purpose would be served by cancellation of the Circular.

Hydrophobia and the Pasteur Treatment.

Mr. FREDERICK GREEN asked the Minister of Health how many persons bitten by alleged or suspected mad dogs since the first case of rabies was notified in this country after the war had refused the Pasteur treatment, and if any of those persons had contracted hydrophobia.—Sir ALFRED MOND replied: So far as I am aware there have been only two cases in this country since the armistice in which persons bitten by dogs which were reasonably suspected to be rabid have refused the Pasteur treatment. Neither of these persons developed hydrophobia.

Superannuation of Local Government Officials.

Mr. MYERS asked the Minister of Health whether he would be able at an early date to give effect to the promise made by his predecessor and introduce a Bill making provision for a national scheme of superannuation for Local Government officials.—Sir ALFRED MOND replied: As I have previously stated in reply to questions, the Government regret that they cannot proceed with this matter at the present time in view of the charges which the scheme would impose upon the rates.

Suffering of Mothers and Children in Ireland.

Viscountess ASTOR asked the Chief Secretary to the Lord Lieutenant of Ireland whether he had received representations as to unnecessary suffering caused to expectant mothers and to women with new-born children through certain police and military regulations in Ireland; and whether he would consider the appointment of a committee of medical and infant-welfare experts to consult with the military authorities as to the best methods of obviating or minimising such suffering.—Mr. HENRY (Attorney General for Ireland) replied: My right honourable friend the Chief Secretary has received no representations of this nature and has no reason to think that there are any grounds on which the appointment of a committee such as is suggested would be justified. He will be glad, however, to consider any representations] that may be made to him on the matter. All doctors and nurses who choose to apply for curfew permits can obtain them. Doctors and nurses are also expressly exempted from motor restrictions and can use motor vehicles without restriction as to distance or time.

Maternity Welfare.

Captain WEDGWOOD BENN asked the Prime Minister the amount which would be involved by the State annually by the ratification of the maternity convention, as estimated by the Government; upon what weekly sum the Government had based the full and healthy maintenance grant for mother and child; and whether the annual estimate had been worked on a contributory or non-contributory basis.—Sir ALFRED MOND (Minister of Health) replied: I am having laid as a White Paper a Memorandum by the Government Actuary on the Washington Draft Convention concerning the employment of women before and after childbirth. The Memorandum deals with the points raised by the honourable Member.

Captain WEDGWOOD BENN asked the Minister of Health the number of women industrially employed who received maternity benefits under the Health Insurance Act for the last year for which returns were available; and the total amount paid out in maternity benefits for industrially employed women in that year.—Sir ALFRED MOND replied: The information as to numbers is not available, and could only be obtained by calling for a special return from all societies and branches. The amount paid as maternity benefit to employed women in England and Wales for the year 1920 in respect of their own insurance was approximately £230,000. In addition, £160,000 was paid as maternity benefit to women who were entitled to special benefits on cessation of employment on or after marriage.

Dentists Bill.

The Dentists Bill was read a second time and committed to a Standing Committee.

Scottish Midwives Order.

The House approved the Scottish Board of Health (Midwives (Scotland) Act, Transfer of Powers from Secretary of Scotland) Order, 1921.

THURSDAY, MAY 12TH.

MINISTRY OF HEALTH VOTE.

The House went into Committee of Supply on a vote of £15,245,093 for the expenses of the Ministry of Health, Mr. JAMES HOPE in the chair.

Sir ALFRED MOND (Minister of Health) said the activities of the Ministry spread over a wide field, and, dealing with very novel propositions under difficult conditions, naturally afforded room for legitimate criticism. But a great deal of the criticism had neither been constructive nor well informed, nor had it made any endeavour to deal with the difficulties of the situation with which his predecessor and he had been faced. In spite of their difficulties they had succeeded in making a substantial reduction in the estimates this year of over £3,000,000. He was applying himself to the task of seeing whether still further economies could be made. Considerable progress had been made in housing. They were now trying to limit the present scheme, cutting down in outlying districts where the housing need was not so great, and concentrating on the great industrial centres in which the housing need was greatest. He would give 300,000 as the gross figure of houses of different classes. If, however, fewer could be done with he would be prepared to cut it down to the minimum requirements. A subject which had aroused a good deal of criticism and comment in the press was the medical establishment of the Ministry. Whereas the old Local Government Board had a relatively small medical staff and relatively little to do in the way of medical duties, the National Health Insurance had a much larger staff, and when the two were joined together that automatically increased the staff of the Ministry of Health. On April 1st, 1919, the number of pensionable medical men in the Local Government Board and the Insurance Commission of England and Wales was 46. The number at present in the Ministry was 59, or a difference of 13, distributed as follows: Maternity and Child Welfare, 2; Tuberculosis, 2; Venereal Disease, 2; Port Isolation Hospitals, 3; Statutory Medical Services and Intelligence Work, 3; and work taken over from the Home Office, 1. These were additional functions to the work which was being looked after by the medical staff of the Ministry of Health, apart from the newly established regional officers. There were no less than 1800 sanitary authorities which looked to the Ministry for guidance, 114 port authorities, 646 Poor-law unions, 1029 isolation hospitals for infectious diseases, and 4220 public vaccination districts which had to be inspected. There were a vast number of maternity centres and tuberculosis sanatoriums to which the Ministry gave grants, and which also had to be inspected. It might be considered cheaper to hand out money without seeing how it was spent in order to save a little in administration, but if this money which the taxpayer handed over to these various institutions was spent badly they might lose a great deal more than the cost of a few inspectors who went round to see that the money was properly expended. They were not up to their full establishment on the medical services; there were two vacancies, but he did not intend to fill them at the present time. There were also some six temporary appointments, the work of which had lapsed and which it was intended to discontinue for the present. There was also the possibility of the reduction of two more of the permanent established staff, making a total reduction on establishment and non-establishment of between nine and ten. That was as far as they could wisely go at the moment. The health-rate of the country was good. The birth-rate was rising and the death-rate declining. Infantile mortality showed a continued steady decline. The work at the maternity welfare centres with its concomitants, which would require development of pre-natal and post-natal care of mothers, was one of the most beneficent reforms any country could undertake. The number of health visitors had gone up from 1400 to 1700, the number of non-resident centres had risen from 1400 to 1900, the number of maternity homes from 740 to 1200, and the infant hospitals for children under 5 years from 50 to 367. He hoped that they would not economise on the infant life of the country.

Progress in Treatment of Tuberculosis.

They were making very good progress with tuberculosis. They could not build up perhaps in a day, and they might achieve relatively little at a time, but they could be confident that with all the difficulties and all the scepticism that one encountered, if they proceeded on sound lines of sanitation and on reasonable lines of care and treatment, if they proceeded on the lines of teaching people more about hygiene and how to avoid the disease, they could produce great improvement still in the physical, moral, and mental standard of our people. The venereal disease work so far as it had gone was making good progress. It was a very difficult but a very important piece of work. Although he did not believe in covering the country with nothing but posters drawing attention to this matter, and over-emphasising it, he was quite convinced that they must steadily proceed both with propaganda and with treatment. He was considering the issue of a new circular explaining the policy of the Department, which consisted in a sane and moderate view of this complex and difficult problem, which had a moral and a social as well as a medical side. Whilst he was prepared to assist in protecting the health of the nation against this dangerous illness he was not prepared to accede to the demands of those who seemed to regard the question with perfect sincerity and great enthusiasm merely from the medical aspect without taking the wider view. The appointment of some 33 medical referees whose duties were largely connected with the examination of members of Approved Societies for National Health Insurance had received a very considerable amount of criticism in the press. These appointments were really made as long ago as 1914 by that House. It was very difficult sometimes to determine whether a man was malingering, or whether he was fit to go back to his work. There was always a danger, he would not say of a bias on the part of his own medical attendant to give him the benefit of a doubt, but it was in the interests of the Approved Societies, of the State and the community, and really of the man himself, that he should go back to his normal life as quickly as possible. That was the work which the medical referees were largely occupied in doing. He had some doubt as to their utility when he came to his present office, and not being in the habit of merely accepting statements presented to him by other people, he went into the question himself. He asked over six medical referees in different parts of the country to come and see him, and he was very much impressed with the value of their work and with the way in which it was appreciated both by Approved Societies and the most intelligent of the ordinary general practitioners in the districts in which they worked. They acted also to a considerable extent as consultants, and were ready to act in that capacity to panel doctors when they had more than ordinary difficulty. He did not believe that their presence was resented by members of the general medical profession. They had not been acting very long, and they were only engaged as an experiment for a certain number of years; but as far as he could see at present they were doing good and useful work, and it would be a very great mistake under the pressure of clamour or prejudice now to do away with a very fruitful source of development of this work, by men very carefully chosen and very able, before anyone had had time to judge how far the work was really going to be of utility to the people. He believed that there was a great future before the Ministry of Health, which was only in its infancy. He hoped that one day research would be associated with the Ministry, for research was going to be one of the most fruitful of developments. He felt very greatly the responsibility of the position in which he was placed. There was a great work to be done, and if they could assist to put up a few small stones of the great building of national wealth and national health, and so endeavour to make disease a thing of the past, when illness will be a forgotten tradition and when people would wonder how they endured the present sanitary surroundings, the time spent would not be in vain.

Improvement of the Panel Service.

Sir **WATSON CHEYNE** asked what alteration, if any, was to be made in the medical services? He presumed that something would be done, because they knew that the panel service could be improved, and it would lie between improving it and introducing some new service—a form of State medical service. Personally he favoured finding out what the defects of the panel service were and trying to improve it rather than scrapping it and introducing a new service which certainly would not be at all favourable to the medical profession. Various things were required to bring the panel system more into the condition in which it ought to be. Much assistance was required in helping the medical men to diagnose their cases and also in regard to certain other matters. Various accusations had been made against panel doctors—chiefly of negligence, imperfect diagnosis, and so forth. His practice had been almost entirely in consultation with other doctors, and he had never come across any evidence of the kind in private practice. At the same time he could quite believe that it might be possible in a few cases that the statements might be more or less justified. When the Insurance Act was first under consideration he was always very doubtful about the question of medical benefit. He welcomed the idea of insuring against sickness. so as to provide money to tide over the sickness and so forth; but he very much questioned the advisability of the panel system as regarded the services of doctors. His belief was that the panel service could be very much improved in various ways. He believed that the one thing wanted to put things right was to increase the free choice of doctors. He wished to call attention to the question of research. He understood that the Medical Research Committee was ready to assist the Ministry of Health in any way it could. It was up to the Ministry to help any of their staff who wished to do research, and not to have to go to another body and ask leave. The existence of a proper research department was extremely necessary for the future of the Ministry. At present very little was being done. He mentioned these matters in the hope that the Minister would tell him that something was contemplated in that direction.

Mr. **IRVING**, a Socialist Member, protested against the Circular No. 185 issued by the Ministry containing the official declaration of policy in regard to maternity and child welfare. The circular, he said, was an attempt to save money, but if money could be saved along these pettifogging lines it would be quite infinitesimal, and the inevitable result would be that they would damage infant life and infant welfare. He objected to the provisions with regard to inquiries as to the necessity of families applying for milk for their children, or for expectant and nursing mothers. The inquisitorial methods adopted were too stringent.

Mr. STEWART raised the question of the insanitary conditions arising in connexion with caravan encampments, and urged that the Ministry should do more than they had done to safeguard the community against the possibilities of disease and epidemic from this source.

Too Much Economy.

Lieutenant-Colonel FREMANTLE said that what they had to aim at was a satisfactory blend between the attitude of those who limited themselves to their enthusiasms for public health, and of those who looked only at the side of economy. Zeal for economy had become a craze and had gone too far. It might result in the loss of a very large amount of life. He hoped that the Minister with his fresh eye and business-like mind would review not only the medical staff—as already he seemed to have done very thoroughly—but also the administrative staff at his office. He did not say that it was necessarily excessive, but when they saw a general clerical staff numbering 1593, including 477 assistant clerks, 301 women clerks, 276 writing assistants, with quite an unusual proportion of senior officers on the administrative side, one was bound to gain a certain impression, especially if one had experience of the local administration of public health. The only strong criticism against the Ministry was that there was too much red tape, too much letter writing, and too much clerical and filing work. There should be a checking committee in each office composed of members of the existing staff, whose duty it should be to decide the particular returns that were absolutely necessary. He could not understand the canard that was going round the press that the Ministry of Health inherited from the Local Government Board a staff of only four medical officers. During the 15 years that he was a county medical officer of health he had frequently to go to the Local Government Board, and he was aware of at least 15 different medical officers.

Dr. ADDISON (Minister without Portfolio): In 1918 there were 46—namely, 38 in the Local Government Board and 8 in the Insurance Department—not 4 as stated.—Lieutenant-Colonel FREMANTLE, continuing, said he agreed that the Medical Research Department of the Privy Council should be in touch with the Ministry of Health; if it was not it was a scandal. Although the improvement in vital statistics was due to a very large number of causes which they could not describe definitely as part of the health administration, there was no question that they were all centred round and stimulated, if not actually initiated and carried through, by the work of the whole organisation which had its pivot and centre in the Ministry of Health. The death-rate itself had been reduced very largely since the Ministry came into operation. It was about 13 or 14 per 1000 before the war and went up during the war to about 15 per 1000, and it had gone down in the last two years to 13·8 and 12·4, the figure for last year. Still more the infantile mortality figures must be very largely attributed to the work of the maternity and child welfare centres. The mortality had gone down to 80 per 1000.

Major FARQUHARSON said his candid opinion was that the housing notion had been overdone from the first. It was greatly due to a mixture of politics and sentiment. It was one of the most unfortunate positions that housing schemes should have been part of the work of the Ministry of Health. The medical staff of the Ministry doing expert scientific work, men of trained experience and sound education, many of whom had given their lives to the work, were getting collectively a sum rather less than one-third of what was being paid to this mushroom growth in connexion with housing. Instead of the medical staff being paid more money for 1921–22 it was actually getting less. Last year they were paid £106,907, and it was proposed to pay them this year £99,571. These 80 or 90 medical officers, who had recently been appointed to supervise and superintend the services rendered to something like 6,000,000 or 7,000,000 insured persons, had to bring themselves in liaison with something like 12,000 or 13,000 doctors. They had the spending of something like £9,000,000 per annum, and yet the paltry sum of something like £100,000 was being spent on the whole medical staff of the Ministry, while a sum of £300,000 was spent upon this excrescent mushroom growth in connexion with housing. He appealed to the Minister without portfolio not to cheese-pare in the direction of cutting down the medical staff of the Ministry. These men were very eminent men who had acquired a reputation in the profession before they entered the portals of the Ministry. If they compared the expenditure on research in this country with that of the continental nations it was perfectly ludicrous. He thought no line of public health offered a greater hope of magnificent and early results than infant welfare and maternity. As regards tuberculosis, the question was entirely an uncertain one. It was entirely experimental, and the whole question of sanatorium treatment had broken down. He appealed to the Minister to introduce a limit in this connexion. The most recent scientific inquiries went to show that in this country, at all events, it would be absolutely impossible to have a tubercular-free population. He believed that the trend of thought, experiment, and scientific inquiry was how far tuberculosis, instead of being the horrible scourge that many people regarded it, was in essence part of our equipment to withstand the severity of our climate.

Major MOLSON thought that the medical referees were very necessary for panel practice, and that the expenditure on them was very economical. He urged that much more should be spent on research.

The Minister's Reply.

Sir ALFRED MOND, replying to the debate, said that the new medical service of providing milk for expectant mothers and infants had been grossly misused. All that Circular 185 did was to require strict control of milk supplied to nursing and expectant mothers, and to place under medical supervision the distribution of this milk, which was given as a medicine. As regards the dangers arising from caravans, those vehicles at present numbered about 1100, of which 25 per cent. were occupied throughout the year. The Department had made two medical inspections of them during the past 10 years. But it was the duty of the local authorities to deal with this matter. All that the Ministry could do at present they were doing. There was no intention, except in the imagination of some people who seemed to belong to the psycho-analyst school and who discovered quite non-existent intentions in the minds of other people, of starting a vast system of State Medical Service. They were working on the lines of endeavouring to improve the panel system where it was capable of improvement, and steps were being taken in that direction. The panel had been lessened. There had been too many people on some panels. They were making improved regulations in regard to surgeries, bringing them in harmony with the best of the practitioners on the panel system. The system might be subject to criticism, but on the whole it had not worked so badly, and the medical profession had a great desire to do their best. He thought there was a good deal to be said for associating the Ministry with medical research in a more direct manner. The question of voluntary hospitals had been giving him very grave anxiety as well as to his predecessor. He expected the Cave Report towards the end of this month. He was extremely sorry that certain of the large hospitals had considered it necessary, in view of the fact that report of this committee was very closely impending, and that the Government were bound to take action on that Report speedily, to close these large numbers of beds, whereas perhaps in a few weeks' time the crisis might be past. He did not think anyone could reasonably ask him or the Cabinet to bring forward a scheme during the next few days. On the other hand, the Approved Societies had already set aside £250,000 to be paid during five years out of their surplus. He should have thought it would have been possible for the hospitals to have got their bankers to continue to advance the relatively small sum that might be necessary to carry them over the last few weeks. He still wondered whether something could not be done in that direction before final steps were taken. He hoped the directors of the hospitals would hold on a little longer until the Government had had an opportunity of studying the Cave Report and acting on it.

The vote was agreed to.

Accommodation at St. Dunstan's.

Mr. FREDERICK HALL asked the Minister of Pensions how many men blinded in the war had been refused admission to St. Dunstan's in the last two months, and whether, in view of the fact that the accommodation for blinded soldiers at St. Dunstan's was being seriously curtailed, the Government was making any provision for the training of these men in new occupations suitable to their condition.—Mr. IAN MACPHERSON replied: I am informed that accommodation at St. Dunstan's is being curtailed only because the requirements are diminishing, and that no man whose blindness is due to his war service has been refused admission.

Treatment of Bilharziasis.

Mr. GRATTAN DOYLE asked the Minister of Pensions if he was aware that Dr. Christopherson's antimony treatment was now accepted as a certain cure for bilharziasis; that the Australian Government, after segregating all returned soldiers infected in Egypt, had completely stamped it out by this method of treatment; that there were still a number of men in this country who were infected during the South African war, and were still sufferers, but who were debarred from treatment by the Ministry because they had not served, in many cases because of this disease, in the recent war; and if there was any valid reason why these men should not have an exception made in their particular favour and receive treatment.—Mr. IAN MACPHERSON replied: I am fully in sympathy with my honourable friend's suggestion, concerning which I am in communication with my right honourable friend the Secretary of State for War.

Liquor Control.

Replying to questions by Sir J. BUTCHER, Mr. LLOYD GEORGE (Prime Minister) stated that the Government had decided that the Liquor Control Board should be placed under the Parliamentary control of the Parliamentary Under Secretary to the Home Office (Sir J. Baird) who would be chairman.

Opium Traffic Advisory Committee.

Mr. GILBERT asked the Lord President of the Council whether he would give the names of the international advisory committee appointed by the Council of the League of Nations to advise on the execution of the agreements in regard to the traffic in opium and other dangerous drugs, and also the names and qualifications of the three medical and technical experts appointed to assist the committee.—Mr. BALFOUR replied: The composition of the Advisory Committee on the Traffic in Opium is as follows:—

Representatives of Governments.—Monsieur W. G. Van Wettum, ex-Director of the Opium Traffic Service in Dutch Indies (Netherlands); Sir Malcolm Delevingne, of Home Office (Great Britain); Monsieur Kahn, formerly French Minister in Siam (France); Mr. J. Campbell, of India Office (India); His Excellency A. Ariyoshi, Japanese Minister at Berne (Japan); His Excellency Tang Tsai-Fou, Chinese Minister at Rome (China); His Excellency Prince Charoon, Siamese Minister at Paris (Siam); His Excellency Bartholomeu Ferreira, Portuguese Minister at Berne (Portugal).

Assessors.—Sir John Jordan, formerly British Minister at Peking; Monsieur Brenier, French Delegate to the International Opium Conference at The Hague in 1912, and at present Director-General of the Services of the Chamber of Commerce at Marseilles; Mrs. Hamilton Wright, widow of Dr. Hamilton Wright, American Delegate to the International Opium Conference at The Hague.

Sir J. D. REES: When the Council of the League of Nations has received this advice, and, if it accepts the advice, will it then become binding upon anybody; and, if so, upon whom?—Mr. BALFOUR: What will happen if and when the advice is accepted will be a matter for the consideration of the Council.

Arsenobenzol Treatment of Venereal Diseases.

Mr. ROBERT RICHARDSON asked the Minister of Health if he would grant a return of all the cases of death arising from ill-effects of the arsenobenzol treatment of venereal diseases which had been reported to his department since the commencement of the public treatment of these diseases; and if in future he would arrange for such particulars to be recorded in his annual report, or in that of his chief medical officer.—Sir ALFRED MOND replied: Twenty-one deaths have been reported to my department as following the administration of arsenobenzol compounds in treatment centres of venereal diseases. Further inquiries show that in three of these cases death was not due to the administration of the drug, and that in five other cases it was doubtful how far the drug had contributed to the fatal result. In the last complete year for which figures are available the number of deaths in which the administration of the drug may have been a contributing cause represents 1 in approximately every 4300 patients treated for syphilis, and 1 in approximately 30,000 injections of these drugs. I will consider the suggestion in the last part of the question.

Lock-up Medical Practices.

Mr. GRATTAN DOYLE asked the Minister of Health whether his attention had been drawn to the increasing numbers of what were known as lock-up medical practices, where panel medical practitioners saw panel patients at fixed hours only, as they (the doctors) only had consulting-rooms there, while they resided it might be miles away, out of reach of a panel patient in an emergency; and whether, in view of the hardship thereby incurred by the patient, he would consider the taking of necessary action in this matter of urgent public interest.—Sir ALFRED MOND replied: My attention has been drawn to one or two cases of the kind referred to in the question which are under investigation. If my honourable friend is aware of any case of the kind I should be obliged if he would furnish me with particulars, as the regulations make adequate provision for dealing with such cases.

Public Health (Tuberculosis) Bill.

The House considered the Lords Amendments to the Public Health (Tuberculosis) Bill.—Sir ALFRED MOND explained that the only amendment of any real substance was a new Clause with respect to the institutional treatment of seamen. He was glad to say that they had come to a satisfactory arrangement which would be of great benefit to the seamen of this country in the future. The amendments were agreed to.

Supplies of Petrol.

Mr. CLOUGH asked the Minister of Transport what supplies of petrol existed in this country; and whether they were adequate for all the immediate needs of the country, assuming that due care in use was taken.—Sir P. LLOYD-GREAME (Parliamentary Secretary to the Board of Trade) replied: The supplies of petrol in this country are at present unusually high. The answer to the second part of the question is in the affirmative.

Protection of Women and Young Persons Bill.

Mr. WIGNALL introduced a Bill "to make further provision for the protection of women and of young persons of both sexes from sexual immorality, and from conduct akin thereto, or connected therewith, and with respect to prostitution and brothels, and to amend Sections 58 and 59 of the Children Act, 1908." The measure was read a first time.

FRIDAY, MAY 13TH.

Inoculation Laboratories at Beckenham.

Mr. HOOD asked the Minister of Health whether he was aware that a private firm proposed to use Langley Court, Beckenham, as laboratories for the purpose of the cultivation of germs and the inoculation of horses and other animals in order to make diphtheria and other serum; whether over 60 animals had already been assembled on the premises for the purpose; whether these operations would constitute a danger to the inhabitants of the district; and what action he proposed to take in the matter.—Sir ALFRED MOND replied: I am aware of this case. A local inquiry has been held by one of my inspectors and his report is now under my consideration.

Bastardy Bill.

The Bastardy Bill was read a second time and committed to a Standing Committee.

Medical News.

UNIVERSITY OF LONDON, UNIVERSITY COLLEGE.—Three public lectures on the History of Chemistry in the Nineteenth Century will be delivered by Sir William Tilden, F.R.S., in the Chemistry Theatre of the College, on Friday, May 27th, June 3rd and 10th, at 5 P.M.

UNIVERSITY OF MANCHESTER.—The following appointments have been made: Dr. Albert Ramsbottom as Professor of Clinical Medicine. Dr. Ramsbottom is physician to the Manchester Royal Infirmary and lecturer on clinical medicine in the Victoria University. Lecturer in Histology, Miss Ruth Fairbairn; Assistant Lecturers in Physics, Mr. J. C. M. Brentano and Mr. H. Lowery.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—An extraordinary Comitia of the Royal College of Physicians of London was held on May 12th, the President, Sir Norman Moore, occupying the chair, when the following gentlemen, elected to the Fellowship at the last meeting, were formally admitted as Fellows :—Dr. C. O. Hawthorne, Dr. C. H. Melland, Dr. J. G. Emanuel, Dr. A. E. Barnes, Dr. J. P. Hedley, Dr. J. A. Torrens, Dr. A. J. Clark, Dr. A. Feiling, Dr. R. H. Steen, Dr. C. M. Wilson, and Dr. G. E. S. Ward.—The Committee of Management reported having received from Sir Charles Ballance, the visitor appointed by the Royal Colleges to inspect the examinations, a full and interesting report on the examinations of the Egyptian Medical School and Hospital at Cairo, and on the teaching at the school and hospital. The Committee expressed the opinion that the examinations and course of education justified the Royal Colleges in continuing their recognition of the school.

ROYAL COLLEGES OF PHYSICIANS OF LONDON AND SURGEONS OF ENGLAND.—At a meeting of Comitia of the Royal College of Physicians on April 28th and of the Council of the Royal College of Surgeons on May 12th Diplomas in Public Health were conferred, conjointly, upon the following candidates:—

G. J. Bowen, Middlesex; I. G. de Zilva, Madras and Roy. Inst. Public Health; A. W. F. Edmunds, King's College; J. J. Gasperine, St. Bart.'s and Roy. Inst. Public Health; M. Gross, Westminster and Roy. Inst. Public Health; A. C. Hancock, Guy's and Univ. Coll.; R. H. Liscombe, J. B. Low, and J. J. MacDonnell, Univ. Coll.; E. F. W. Mackenzie, (Edinburgh and Royal Army Med. Coll.; Gladys M. Miall-Smith, Royal Free and Univ. Coll.; A. H. Patel, Bombay and Roy. Inst. Public Health; A. J. Patterson, Dublin and Haslar; G. H. Pearson, London and King's Coll.; A. L. H. Rackham, Middlesex; B. K. Ray, Calcutta and Univ. Coll.; A. C. Renwick, Edinburgh and King's Coll.; P. C. Sen, Calcutta and King's Coll.; R. J. L. Sladen, Univ. Coll.; M. Subramanyam, Bombay and King's Coll.; R. Swyer, Univ. Coll.; W. B. B. Taylor, London and Royal Army Med. Coll.; and H. J. Thomas, Univ. Coll.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH, ROYAL COLLEGE OF SURGEONS OF EDINBURGH, AND ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—At recent examinations of the Board the following candidates completed the examination, and were admitted Diplomates in Public Health:—

Thomas Pullar and Janet Bisland Higgins.

The following candidates passed in Part I.:—

Ellen D. Anderson, William Cunningham, Robert J. Peters, Andrew Davidson, Mary C. Walker, Marguerite Linck Sclanders, William H. Wallace, William D. MacKinnon, Edward M. E. Cumming, Andrew M. Davidson, Campbell L. Miller, David Heard, David Fyfe, William McKendrick, Helena E. Barrett, Samuel J. Henderson, and John Frew.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.—The annual provincial meeting of this Society will be held on Saturday, June 11th. Members will assemble at the house of the Society at 10.30 A.M. and proceed by motor coach to Hatfield House, which will be visited by invitation of Lord Salisbury. Afterwards the party will go on to Welwyn Garden City, where they will be entertained at luncheon by the President of the Society, Lieutenant-Colonel F. E. Fremantle, M.P. The afternoon will be spent in viewing the Welwyn housing and town-planning schemes until 4 P.M., when Mrs. Fremantle has invited members to tea at Bedwell Park. As it is necessary to make early arrangements for motor coaches, members who intend to be present should give prompt notice to the Executive Secretary, 1, Upper Montague-street, Russell-square, W.C. 1, stating if they will be accompanied by ladies. A remittance of 10s. 6d. for each motor coach ticket should be forwarded with the application.

MEDICAL SOCIETY OF LONDON.—On Monday, May 23rd, at 8 P.M., the annual general meeting will be held. At 9 P.M. the annual oration will be delivered by Lord Dawson, of Penn, K.C.V.O., on the Colon and Colitis.

MEDICO-LEGAL SOCIETY.—A meeting of this Society will be held at 11, Chandos-street, London, W., on Tuesday, May 24th, at 8.30 P.M., when a paper will be read by Mr. W. G. H. Cook on the Liability of the Insane in Respect of Civil Wrongs.

LONDON HOSPITAL MEDICAL COLLEGE: *Surgical Unit.*—A special course of ten lectures on Advanced Surgery will be given on Tuesdays and Thursdays, at 4.15 P.M., in the Unit Lecture Theatre of the hospital, beginning on June 7th, when Mr. Russell Howard will give the first of two lectures on Diseases of the Breast. Subsequent lectures will be announced in our Medical Diary. Post-graduates and senior students are invited to attend.

AN International Congress on the History of Medicine will be held at Paris on July 5th, and will be presided over by Professor E. Jeanselme and Professor W. Menetrier. There will be lectures, discussions, and excursions. All who possess documents or instruments of interest are invited to lend them to the organisers for temporary exhibition.

SUMMER POST-GRADUATE MEDICAL COURSES.—*University of Paris.*—A vacation post-graduate course will be held during July at the Clinique Médicale de l'Hôtel-Dieu under the auspices of the Faculty of Medicine. The course will deal with recent additions to our knowledge of clinical practice and the application of current laboratory methods of diagnosis. It will begin on Monday, July 4th, and will be under the direction of Professor (agrégé) Maurice Villaret, with the collaboration of Mr. Herscher, Mr. E. Guilleminot, Mr. Lippmann, Mr. Jomier, Mr. Chabrol, Mr. Brin, Mr. Henri Bénard, Mr. Dufourmentel, Mr. F. Saint-Girons, Mr. Coury, Mr. Paul Descomps, Mr. Dumont, Mr. E. Deval, Mr. H. Dausset, Mr. L. Durey, Mr. Gérard, Mr. Lagarenne, and Mr. Comandon. A week's trip to spas in the Pyrenees will be arranged, starting on July 9th, and the studies in Paris will be resumed on July 18th. Details and programme of this trip may be obtained from M. le Dr. Dausset, Clinique medicale de l'Hôtel-Dieu, Paris. A certificate will be issued to those who have taken part in the course, for which the fee is Fr.150.

St. Bartholomew's Hospital and College.—A course of instruction for qualified practitioners will be given during the summer vacation, beginning on Monday, July 18th, and ending on Saturday, July 30th, with the object of affording practitioners the opportunity of attending the practice of a large metropolitan hospital and medical school for a short period, and of receiving systematic teaching from members of the hospital staff at a time when ordinary lectures and classes are mainly in abeyance and comparatively few students are in attendance. By payment of a composition fee of £8 8*s.*, a practitioner will be entitled to attend, between the dates given above, any of the special classes, except clinical pathology and bacteriology, and the ordinary hospital practice, including wards, out-patients, special departments, operations and post mortems. Practitioners who are perpetual students of St. Bartholomew's Hospital will be admitted to the post-graduate classes, except clinical pathology and bacteriology, on payment of a fee of £6 6*s.* An extra fee of £2 2*s.* will be payable by any practitioner who attends the class in clinical pathology and bacteriology. Fees are due in advance, and cheques should be made payable to the Dean, Dr. T. W. Shore.

Glasgow Post-Graduate Medical Association.—A comprehensive course of instruction has been arranged for medical practitioners, extending from May till October, 1921. Most of the hospitals in Glasgow are taking part in the scheme, and the classes, as far as possible, have been arranged so that a practitioner who so desires may be enabled to occupy the greater part of each day attending classes. The classes are open to all qualified medical practitioners, and will be conducted independently of the undergraduate courses. A practitioner may enrol for one or several classes, and may attend for one or more months as desired. The classes are specially designed to suit the requirements of general practitioners, but in order to meet the needs of graduates and others who wish to obtain a closer acquaintance with hospital work arrangements have been made whereby a limited number may become attached to wards or out-patient departments, nominally as clinical assistants, for definite periods throughout the year. Intending students must enrol and pay their fees at the institutions in which the particular classes are held. Further information will be supplied on application to Dr. A. M. Kennedy, secretary, Post-Graduate Medical Association, University, Glasgow.

ROYAL MEDICAL BENEVOLENT FUND.—At the last meeting of the Committee, held on May 10th, 21 cases were considered, and £308 voted. The following is a summary of the cases relieved :—

Daughter, aged 54, of M.R.C.S.Eng. who practised in Liverpool and died in 1872. Applicant had a stroke suddenly in April, 1920, which affected her left side, and was taken to Charing Cross Hospital, where she remained for four or five months; considered incurable was sent to a nursing home and the fees are being paid by three sisters whose incomes are extremely limited; she also receives £8 15s. from an uncle. Prior to her illness applicant acted as a companion and also taught music, French, and German. Her sister, aged 53, also is suffering from paralysis and is in a nursing home, she also has applied for help from the Fund. Voted £18 in 12 instalments.

Daughter, aged 73, of M.R.C.S. Eng. who practised in the R.A.M.C., and was also a Resident Medical Officer in London later, and died in 1891. Owing to a limited income and having to help towards the expenses of a bedridden brother in a nursing home applicant has asked the Fund to help her to supplement her Grice Annuity of £40 and the £4 she was paid for making fancy bags and painting little water-colour sketches. Since the war have had to pawn family things and have to pay a heavy rate of interest. Her sister applied to the Fund, and the Committee made her a grant of £10. Voted £10.

Widow, aged 25, of M.R.C.S. Eng., 1914, who acted as locum, and in 1918 he was attached to the Russian Red Cross Society and died of typhus while working on a Red Cross train in 1920. Applicant managed to escape from Russia with her little son, aged 4, and arrived in England without means and is at present being supported by friends. She is very anxious to be self-supporting, and to this end has applied to the Fund for help and to advise in placing her son in a school. Voted £10.

Widow, aged 55, of L.F.P.S. Glasg. who practised in Liverpool and was acting as surgeon on board when torpedoed and all were lost. Applicant receives a pension from the War Risk Association of £5 6s. 8d. per month. Rent 11s. per week. Her youngest son, who is in the Merchant Service, is now unfortunately out of work, and applicant finds it difficult to support two on her small pension. Voted £10 in two instalments.

Widow, aged 80, of L.R.C.S. Irel., L.R.C.P. Edin. who practised at Benfleet and died in 1918. Her sole income consists of £50 per annum derived from insurance. Applicant asks for help to supplement this amount, as her rent is £10 and her board costs 15s. per week. Voted £18 in 12 instalments and also £6.

Widow, aged 55, of L.S.A. Lond. who acted as locum and died in 1921. Owing to illness applicant's late husband was helped by the Fund, and now his widow asks for help, as she has no settled income and lets two unfurnished rooms to help to pay her way. She receives from friends about £26 per annum and 7s. 6d. for her rooms, and her rent is 17s. 6d. per week. Voted £10 in two instalments.

Subscriptions may be sent to the Hon. Treasurer, Sir Charters J. Symonds, K.B.E., C.B., F.R.C.S., at 11, Chandos-street, Cavendish-square, London, W.1.

SCOTTISH CONSULTATIVE COUNCIL AND THE MEDICAL GUILD.—Our Scottish correspondent writes: Criticism of the scheme of medical service for Scotland, presented last January to the Scottish Board of Health by the Consultative Council on Medical and Allied Services, was, as your readers already know, widespread. The Medical Guild took the opportunity of obtaining the views of the medical profession in Scotland on certain specific points. Two questions were submitted in the form of a referendum. One of these asked for approval or otherwise of the attitude of the Guild expressed thus: "Matters will be righted only when the State ceases to interfere with medical attendance on sick people other than those who belong to the necessitous classes, so long as the sick are not a danger to the community by reason of infectivity." The other ran: Do you approve of the proposed extension of National Health Insurance (Recommendation 4)? Replies favourable to the policy of the Guild required "Yes" for Question 1 and "No" for Question 2. The returns so far to hand number 1331, and are summarised by the Guild as follows: Of that number 1105, or approximately 83 per cent., voted "Yes" to Question 1 and "No" to Question 2; 165, or approximately 12½ per cent., answered both questions in the negative; the remaining 61, less than 5 per cent., voted "No" for Question 1 and "Yes" for Question 2, and thus this small minority only were in favour of the recommendations of the Consultative Council. The large majority, 1270—i.e., 1105 plus 165, over 95 per cent. of the total vote, were therefore opposed to further extension of the National Health Insurance Act, which is made the basis of the Consultative Council's scheme. In many cases replies were accompanied by emphatic protests against the nationalisation of the practice of medicine, notably from men who have had ample experience of work under a State medical service similar in outline to the scheme proposed by the Consultative Council. The statement of the Guild concludes: "It is difficult to give an accurate statement of the number of men at present serving under the National Insurance Act who voted with the above large majority, but the returns received from certain working-class districts prove that the proportion was large. The result of this referendum demonstrates that a large section of the pro-profession in Scotland is opposed to the provision for medical services recommended in the Interim Report, including the extension of the National Health Insurance Act."

LONDON DERMATOLOGICAL SOCIETY.—A meeting of this Society will be held at 4.30 P.M. on Tuesday, May 24th, at St. John's Hospital, 49, Leicester-square, London, W.C., when clinical cases will be shown.

MEDICO-PSYCHOLOGICAL ASSOCIATION OF GREAT BRITAIN AND IRELAND.—The next quarterly meeting will take place on Tuesday, June 7th, at the Maudsley Hospital, Denmark Hill, S.E., under the presidency of Dr. W. F. Menzies, at 3 P.M. Sir Frederick Mott will deliver the second Maudsley Lecture at 4.30 P.M.

OPHTHALMOLOGY IN RELATION TO OCCUPATION.—A course of extension lectures on Ophthalmology in Relation to Trades and Occupations has been arranged in connexion with the Post-Graduate School of the Royal London (Moorfields) Ophthalmic Hospital to be given at the Royal Society of Medicine at 5.30 P.M. Monday, Tuesday, and Wednesday, May 23rd to 25th, Illumination, by Mr. J. Herbert Parsons, F.R.S.; Thursday, May 26th, Practical Illumination, by Mr. L. Gaster, secretary of the Illuminating Engineering Society; Monday, May 30th, Miners' Nystagmus, by Dr. Lister Llewellyn; Tuesday, May 31st, Injuries due to Penetrating Foreign Bodies, by Mr. Charles Goulden, F.R.C.S.

AT this year's annual dinner of the Leeds Caledonian Society, Dr. Wardrop Griffith, the President, in the name of the Society, handed to the treasurer of the infirmary a cheque for £1200 and held out hopes of the sum being increased to £1500. This would enable three cots to be endowed in the name of the Society in the new department of the infirmary. It is hoped that this example may be followed by others.

CARE OF SICK CHILDREN IN LEEDS.—From time to time philanthropic persons in Leeds make their voices heard in the plaint that there is "no hospital for children." There is now no separate building called a Children's Hospital, but Leeds has a Children's Hospital within the walls of the General Infirmary. In connexion with the increase in the number of beds, which has been secured by the completion of the King Edward Memorial Extension, the board of this infirmary has had under consideration plans for increasing the accommodation for children and for the segregation of young patients in one department. Wards 6, 8, and 10, all of which are on the level of and communicate directly with the North Terrace, are to be allotted to the children's department. They are to be connected by bridges at their further end so as to ensure the safety of the children in the event of fire, as well as to provide open-air accommodation for patients. Certain alterations and extensions on the terrace will provide a semi-open-air ward with accommodation possibly for 20 patients. It is hoped that in the near future there will be about 120 cots in all. Of the three wards one is to be allotted to medical cases, one to surgical cases, and the third is to have 19 surgical, 8 ophthalmic, and 6 aural cases; the allocation of the 20 beds on the terrace has not as yet been considered. It is apparently the belief in well-informed medical circles in Leeds that the best way to improve the accommodation for children under prevailing conditions is not to try to create a separate institution, but to extend and improve the accommodation at the central institution, and at the same time to increase the already existing accommodation at the semi-convalescent hospitals. Provision must be made for the prolonged treatment both of surgical cases and of certain forms of medical tuberculosis. A source of strength to the Leeds Medical School and to its charitable institutions is the prevailing system of centralisation; and in the best interests of the public, the patients, and the medical school alike it is to be hoped that this will be maintained. A new development in the children's department from which good results may ensue is the rearrangement of the allocation of beds. For some time there has been an out-patient department for the nutritional diseases of children under the age of three years, controlled by one of the assistant physicians, but all children admitted to the wards have come under the charge of one of the full staff. In the future a member of the assistant staff will have two out-patient days, one for the nutritional diseases of young children and the other for children suffering from medical ailments. To him are allotted all the beds allocated to the nutritional diseases of children, and one-fourth of the remaining medical children's beds, while the remaining three-fourths of the medical children's beds are divided between the three members of the full staff. This department of the infirmary has been linked up under Dr. C. W. Vining's direction with one of the centres of the babies' welcome organisation, and thus students are getting valuable experience in a branch of practical study not as yet on the curriculum of most medical schools.

THE MORRISTOWN PHYSIATRIC INSTITUTE.—The Physiatric Institute, Morristown, New Jersey, U.S.A., has been established for the treatment of metabolic disorders, especially diabetes, obesity, Bright's disease, and high blood pressure. The purposes of the Institute are scientific and philanthropic, and treatment is offered to suitable patients whatever may be their financial circumstances. Morristown is situated about 6000 ft. above sea-level; the district is noted for its beauty and climate, the latter being healthy and agreeable all the year round. There is an excellent train service to New York City by the Delaware and Lackawanna Railroad. The site of the Institute is a former large private estate comprising about 200 acres of woodland, lawns, gardens, and farmland. The main building, standing at the highest point of the property, commands views of great charm. A private lake, an 18-hole golf course, tennis and squash-rackets courts, &c., are included in the grounds. The diet kitchen and laboratories are completely equipped and organised for study of each individual case; patients are expected to coöperate seriously in their treatment, and to adhere rigidly to the rules laid down for them.

For well-to-do patients the Institute is said to offer the advantages of a private sanatorium; "worthy" poor patients are received on proper recommendation, and can obtain treatment at lower rates or free, or when able may perform some kind of work for part payment. Scientific research is one of the main aims of the Institute; over 500,000 persons in the United States to-day have diabetes, and the numbers of those suffering from arterio-sclerosis, kidney disease, and high blood pressure are much greater. The principal appeal for funds, which are urgently needed to support and extend both the scientific and philanthropic sides of the work, is made to the patients themselves and to their relatives and friends.

Appointments.

Successful applicants for vacancies, Secretaries of Public Institutions, and others possessing information suitable for this column, are invited to forward to THE LANCET *Office, directed to the Sub-Editor, not later than 9 o'clock on the Thursday morning of each week, such information for gratuitous publication.*

BATTEN, H. E., F.R.C.S., has been appointed Head of the Department of Orthopædics, including Remedial Exercises and Massage, at Charing Cross Hospital.

COATES, V. M., M.R.C.S., L.R.C.P. Lond., Honorary Assistant Physician to the Royal United Hospital, Bath.

FIRMAN-EDWARDS, L., M.B., B.Ch. Cantab., Honorary Pathologist to the Royal Isle of Wight County Hospital, Ryde.

WEBSTER, J. H. D., M.D. Edin., Honorary Physician-in-charge of the Department of Physical Medicine at the Middlesex Hospital.

WHITEHOUSE, B., M.S. Lond., F.R.C.S. Eng., Honorary Obstetric Officer to General Hospital, Birmingham.

Paddington Green Children's Hospital: MORRIS, J. C., M.B., Ch.B. Edin., House Physician; BRUNTON, W. D., M.B., Ch.B. Edin., House Surgeon.

Certifying Surgeons under the Factory and Workshop Acts: FAULKNER, C. D., M.R.C.S., L.R.C.P. Lond. (Stanford-le-Hope); PENHALE, W. P., M.R.C.S., L.R.C.P. Lond. (West Bromwich).

Vacancies.

For further information refer to the advertisement columns.

Adelaide University.—Professor of Zoology. £1100.

Barrow-in-Furness County Borough.—Asst. Sch. M.O. £500.

Bedford County Hospital.—Asst. H.S. £150.

Birmingham, Queen's Hospital.—Hon. Obst. O.

Bootle Borough Hospital.—H.S. £150.

Bury St. Edmunds, West Suffolk General Hospital.—Res. H.S. £200.

Cardiff City and Port Education Authority.—M.O.H. and Chief M.O. £1200.

Chester Royal Infirmary.—Asst. H.S. £175.

City of London Hospital for Diseases of the Chest, Victoria Park, E.—H.P. £125.

Dumfries, Crichton Royal Mental Hospital.—Clin. Path. £400.

Dundee Royal Infirmary.—Hon. Asst. Gynæcol. and Obstet. Dept.

Durham, County Sanatorium, Holywood Hall, Wolsingham.—Asst. M.O. £400.

East Sussex County Council Education Committee.—Asst. Sch. M.O. £500.

Elizabeth Garrett Anderson Hospital, Euston-road, N.W.—Female Asst. P., Asst. Radiologist, H.P., Obstet. Asst., and H.S.'s. Each £50.

Hellingly, East Sussex County Mental Hospital.—Sec. Asst. M.O. £450.

Hospital for Sick Children, Great Ormond-street, W.C.—Clin. Asst. in Venereal Dept. £1 1s. per visit. H.S. £100.

Hull Royal Infirmary.—Asst. H.S. £150.

Hull and Sculcoates Dispensary.—M.O. £450.

Infants Hospital, Vincent-square, Westminster.—Female Res. M.O. £200.

Kensington and Fulham General Hospital, Earl's Court, S.W.—H.S. £100.

Leeds Dental Hospital.—Hon. Asst. Dent. S.

London County Council.—Seventh Asst. M.O. £300.

London Temperance Hospital, Hampstead-road, N.W.—Ophth. S. and Asst. S. Also Res Cas. O. £125.

Maidstone, West Kent General Hospital.—H.S. £220.

Manchester County Asylum, Prestwich.—Asst. M.O. £572 18s.

Manchester, University of, Department of Pathology.—Lecturers in Morbid Anatomy and Morbid Histology, Bacteriology, and Chemical Pathology. £700 each.

Manchester, Whitworth Park Hospital.—H.S. £100.

Middlesbrough Education Committee.—Female Asst. School M.O. £500.

Newcastle-upon-Tyne, Royal Victoria Infirmary.—Hon. Asst. P.

Norwich, Norfolk and Norwich Hospital.—H.P. £200.

Nottingham City Education Committee.—Jun. Asst. Sch. M.O. £537 10s.

Oldham Royal Infirmary.—H.S.'s. £250 each.

Orkney, Eday Parish Council.—M.O. £5 per week.

Prince of Wales's General Hospital, Tottenham, N.—Hon. P. and Hon. Asst. P.

Queen Mary's Hospital for East End, Stratford, E.—Cas. O.

Rotherham Hospital.—Jun. H.S. £150.

Royal Naval Medical Service.—Surg.-Lieuts. 26s. 6d. per diem.

Royal South Hants and Southampton Hospital.—Sen. H.S. £200. Also H.P. £150.

Southampton Free Eye Hospital.—H.S. £200.

South London Hospital for Women, South Side, Clapham Common, S.W.—Temp. (Female) Asst. S.

South Shields County Borough.—Ven. Dis. M.O. £750.

Staffordshire General Infirmary.—H.S. £250.

Sunderland Royal Infirmary.—H.S. £200.

Swansea County Borough.—Asst. M.O. £500.

Taunton and Somerset Hospital.—Sen. and Jun. H.S.'s. £200 and £150.

University College Hospital.—Part-time Anæsth. £150.

Wandsworth Union, St. John's Hill Hospital.—Locum Tenens M.O. £8 8s. per week.

Winchester, Royal Hampshire County Hospital.—Sec. Res. M.O. £150.

York County Hospital.—Third Res. O. £150.

THE Chief Inspector of Factories, Home Office, S.W., gives notice of vacancies for Certifying Surgeons under the Factory and Workshop Acts at Clwt-y-Bont (Carnarvon), and at Washington (Durham).

Births, Marriages, and Deaths.

BIRTHS.

ATTWOOD.—On May 13th, at Glenfern, The Avenue, Southampton, the wife of Dr. H. C. Attwood, of a son.

LYNHAM.—On May 10th, at The Chine, Grange Park, N., the wife of Dr. J. E. A. Lynham, of a daughter.

MOORE.—On May 10th, in a nursing home, Chester, the wife of L. C. Moore, M.R.C.S., L.R.C.P., of a son.

NEVE.—On May 8th, at Barnhill, Bromley, Kent, the wife of Dr. Ernest F. Neve, of a daughter (stillborn).

SHELDON.—On May 13th, at Chepstow Villas, W., the wife of W. Sirr Sheldon, M.R.C.S. Eng., L.R.C.P. Lond., of a son.

MARRIAGES.

HICKINBOTHAM—GODFREY.—On May 10th, at St. Margaret's Church, Lee, S.E., James Ryland Hickinbotham, M.B., to Mary Irene Godfrey.

DEATHS.

KEAY.—On May 9th, at Bodmin, Cornwall, after a long and painful illness, Charles Henry Keay, M.B., B.S., L.R.C.P., M.R.C.S., aged 29 years.

MACDONALD.—On May 8th, at The Haven, Inverness, Thomas Rankin Macdonald, M.B., F.R.C.S.E., late Lieutenant-Colonel, I.M.S.

MICHIE.—On May 11th, suddenly, Dr. William Adam Michie, at 15A, Gower-street, W.C., aged 69.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages and Deaths.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Tuesday, May 31st.

GENERAL MEETING OF FELLOWS: at 5 P.M.
Ballot for Election to the Fellowship. (Names already circulated.)

MEETINGS OF SECTIONS.

Monday, May 23rd.

SECTION OF ODONTOLOGY: at 8 P.M.
Annual General Meeting—Election of Officers and Council.
Casual Communication: Mr. J. Howard Mummery and Mr. G. J. Harborow: A Composite Odontome.
Paper: Mr. A. T. Pitts: The Prophylactic Extraction of the Third Molars.

Tuesday, May 24th.

SECTION OF MEDICINE: at 5.30 P.M.
Annual General Meeting.—Election of Officers and Council.
Discussion: On "Artificial Pneumothorax," to be opened by Dr. Clive Riviere. The following will also take part:—Dr. S. Vere Pearson, Dr. Neville Cox, Dr. Donald Hall, Dr. Jane Walker, and Dr. C. S. Burrell.
Will other Members wishing to speak kindly communicate with Dr. E. P. Poulton, The Downs, Woldingham, Surrey.

Thursday, May 26th.

SECTION OF UROLOGY.
3.30 P.M., at St. Thomas's Hopital: *Operations* by Mr. Cyril Nitch.
8.30 P.M., at 1, Wimpole-street, W.
Annual General Meeting—Election of Officers and Council.
Paper: Mr. V. Zachary Cope: Genito-urinary Symptoms in Acute Appendicitis.
Demonstration: Mr. Swift Joly: Demonstration of a New Operating Cystoscope.

Friday, May 27th.

SECTION OF STUDY OF DISEASE IN CHILDREN: at 5 P.M. (Cases at 4.30 P.M.)
Annual General Meeting—Election of Officers and Council.
Cases will be shown.
Communication: Dr. Hugh Thursfield: The Diagnosis of a Case of Renal Calculus in a Child.

SECTION OF EPIDEMIOLOGY AND STATE MEDICINE: at 8.30 P.M.
Annual General Meeting—Election of Officers and Council.
Papers: Dr. R. J. Reece: Some Observations on the Occurrence of Cow-pox and Human Cases in connexion therewith.
Dr. F. R. Blaxall: Some Notes on the Preparation of Vaccine Lymph at the Government Lymph Laboratory.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.
Monday, May 23rd.—8 P.M., Annual General Meeting—Election *of Officers and Council for 1921–1922. 9 P.M.,* Annual Oration:—Lord Dawson of Penn: The Colon and Colitis. Followed by a Conversazione.

MEDICO-LEGAL SOCIETY, 11, Chandos-street, Cavendish-square, W.
Tuesday, May 24th.—8.30 P.M., *Paper:*—Dr. W. G. H. Cook: The Liability of the Insane in Respect of Civil Wrongs.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, W.C. 1.

MEDICAL SCHOOL.

Monday, May 23rd.—2 P.M., Out-patient Clinic: Dr. Hinds Howell. 3.30 P.M., Lecture:—Dr. A. Turner: Neuroses.
Tuesday, May 24th.—2 P.M., Out-patient Clinic: Dr. Grainger Stewart. 3.30 P.M., Dr. J. Taylor (Lecture Room): Demonstration of Cases.
Thursday, May 26th.—2 P.M., Out-patient Clinic: Dr. Farquhar Buzzard. 3.30 P.M., Lecture:—Mr. Scott: Investigation of Cases of Vertigo. (II.)
Friday, May 27th.—2 P.M., Out-patient Clinic: Dr. Gordon Holmes. 3.30 P.M., Lecture:—Dr. Grainger Stewart: Sciatic Nerve Lesions.

NEUROLOGICAL OPHTHALMOLOGY.

Wednesday, May 25th.—3.30 P.M., Mr. Leslie Paton: Ocular Palsies.
Fee for Post-Graduate Course £7 7s. C. M. Hinds Howell, Dean.

LONDON HOSPITAL MEDICAL COLLEGE (University of London), Turner-street, Mile End, E.
Courses of Lectures:—
A Course of Fourteen Lectures on Psycho-Neuroses, to be given by Dr. M. Culpin in the Clinical Theatre of the Hospital. Open to Students of the Hospital and to Members of the Profession.
Tuesday, May 24th.—5.15 P.M., Lecture VII.:—Dreams.
Friday.—5.15 P.M., Lecture VIII.:—Symptomatology.

Advanced Lectures in Physiology, to Students of the University and to others interested in the subject.
A Course of Eight Lectures on Reception of Sensory Stimuli, to be given by Prof. H. E. Roaf in the Physiology Theatre.
Thursday.—4.30 P.M., Lecture III.

ST. BARTHOLOMEW'S HOSPITAL (University of London), West Smithfield, E.C.
A Course of Eight Advanced Lectures in Physiology, to be given in the Physiological Laboratory, to Students of the University and others interested in the subject.
Tuesday, May 24th.—4.30 P.M., Lecture IV.:—Prof. W. M. Bayliss: The Reaction of the Blood.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.
Monday, May 23rd.—2 P.M., Dr. Simson: Diseases of Women. Dr. S. Pinchin: Medical Out-patients. Dr. Morton: X Ray Department. 5 P.M., Lecture:—Dr. A. Saunders: *Gastric* Disorders in Infants.
Tuesday.—10 A.M., Mr. Steadman: Dental Department. 12 noon, Mr. T. Gray: Demonstration of Fractures. 2 P.M., Dr. Burnford: Medical Out-patients. Dr. Pernet: Skin Department. 2.30 P.M., Mr. Addison: Visit to Surgical Wards. 5 P.M., Lecture:—Mr. B. Harman: Blind and Partly Blind Children.
Wednesday.—*10 A.M., Mr. MacDonald: Genito-Urinary* Department. 12 noon, Mr. Sinclair: Surgical Diseases of the Abdomen. 2 P.M., Mr. Gibb: Eye Department. 2.30 P.M., Mr. D. Armour: Demonstration of Cases (Surgical Wards). 5 P.M., Lecture:—Dr. G. Stewart: Cranial Nerve Palsies.
Thursday.—10.30 A.M., Dr. Simson: Gynæcological Demonstration. 2 P.M., Mr. B. Harman: Eye Department. Mr. Baldwin: Orthopædic Department. 5 P.M., Special Lecture-Demonstration:—Dr. L. S. Burrell: Artificial Pneumothorax (open to all medical practitioners).
Friday.—10 A.M., Dr. Robinson: Gynæcological Operations and Visit to Wards. 11 A.M., Dr. McDougal: Electrical Department. 12.15 P.M., Dr. Burnford: Applied Pathology. 2 P.M., Mr. Banks Davis: Diseases of the Throat, Nose, and Ear. 2.30 P.M., Dr. Pritchard: Visit to Medical Wards. 5 P.M., Lecture:—Sir R. Armstrong-Jones: The Common Forms of Mental Disease.
Saturday.—9 A.M., Dr. Burnford: Bacterial Therapy Department. 10 A.M., Dr. A. Saunders: Medical Diseases of Children. 2 P.M., Dr. Owen: Medical Out-patients. Mr. Sinclair: Surgical Out-patients.
Daily:—10 A.M. Visit of Post-graduates to Wards. 2 P.M., In-patient, Out-patient Clinics and Operations.

LONDON (ROYAL FREE HOSPITAL) SCHOOL OF MEDICINE FOR WOMEN (University of London), Hunter-street, W.C.
Post-Graduate Course of Instruction in Treatment of Venereal Diseases.
A Course arranged by the London (Royal Free Hospital) School of Medicine for Women, the Royal Free Hospital, the Elizabeth Garrett Anderson Hospital and the London Lock Hospital, for the instruction of qualified medical women in the Treatment of Venereal Diseases. The Course will extend over two weeks.
Monday, May 23rd.—2.30 P.M., Miss M. Basden: Visit to Maternity Wards and Labour Department (at the London Lock Hospital, Harrow-road). 5 P.M., Mrs. Rorke, M.B.: Out-patient Cliniques for Women and Children (at the Royal Free Hospital, Gray's Inn-road).
Tuesday.—9.30 A.M., Injections (at the London Lock Hospital, 283, Harrow-road). 2 P.M., Mr. C. Gibbs: Clinical Demonstration and Visit to Wards (at the Female Lock Hospital, Harrow-road). 6.30 P.M., Dr. Ruth Balmer: Out-patient Cliniques for Women and Children (at the Elizabeth Garrett Anderson Hospital, 144, Euston-road, N.W.)
Wednesday.—11 A.M., Dr. D. Thomson: Pathological Lecture and Demonstration (at the London Lock Hospital, 91, Dean-street, W.) 3.30 P.M., Mr. J. E. Lane: Clinical Demonstration by and Visit to Wards and *Out-patient Department* (at the London Lock Hospital, Harrow-road).
Thursday.—2 P.M., Mr. J. E. R. McDonagh: Clinical Demonstration by and Visit to Wards (at the London Lock Hospital, Harrow-road). 5 P.M., Mrs. Rorke, M.B.: Injections (at the Royal Free Hospital, Gray's Inn-road).
Friday.—10 A.M., Mrs. Rorke, M.B.: Treatment Ante-natal Cases (at the Royal Free Hospital). 5 P.M., Mr. J. J. Abraham: Clinical Demonstration, Injections, and Out-patient Clinique for Women and Children (at the London Lock Hospital, 91, Dean-street, W.). 6.30 P.M., Dr. Ruth Balmer: Out-patient Cliniques for Women and Children (at the Elizabeth Garrett Anderson Hospital).
Saturday.—9.15 A.M., Dr. Ruth Balmer: Injections (at the Elizabeth Garrett Anderson Hospital).

QUEEN'S HOSPITAL FOR CHILDREN, Hackney-road, E.
A Course of Post-Graduate Clinical Lectures and Demonstrations in the Board Room of the Hospital, free to Medical Practitioners and Students of Medicine.
Monday, May 23rd.—4 P.M., Mr. M. Vlasto: Tonsils and Adenoids in Children.
Tuesday.—4 P.M., Mr. A. H. Todd: Common Disabilities of the Lower Limbs (other than Paralytic) in Children (I.).
Wednesday.—4 P.M., Dr. G. Bourne: Treatment of Heart Disease in Children.
Thursday.—12 noon, Mr. V. Nesfield: The Treatment of Corneal Opacities by Sub-conjunctival Injections of Phenolaine Solution.

TAVISTOCK CLINIC FOR FUNCTIONAL NERVE CASES, 51, Tavistock-square, W.C.
A Course of Ten Lectures on Elementary Psychotherapy, to be given by Dr. H. C. Miller, at the *Kingsway Hall, Kingsway,* W.C.
Friday, May 27th.—5.15 P.M., Lecture IV.: The Unconscious Motive; The Centre of Analytical Psychology.

INSTITUTE OF PATHOLOGY AND RESEARCH, St. Mary's Hospital, in the Lecture-room of the Bacteriological Department.
A Course of Lectures on Pathological Research in its Relation to Medicine, open to all Members of the Profession and Students.
Thursday, May 26th.—4.30 P.M., Dr. J. A. Murray: Aims and Progress of the Experimental Study of Cancer.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE CLINIC.
Tuesday, May 24th.—4.30 P.M., Lecture:—Mr. Smith: Diagnosis of Rectal Conditions.

MANCHESTER FRENCH HOSPITAL POST-GRADUATE LECTURES, 24, Acomb-street, Whitworth Park.
Special Course of Lectures in Gynæcology.
Wednesday, May 25th.—11 A.M., *Demonstration Operations.*
Thursday.—4.30 P.M., Lecture VII.:—Dr. A. C. Magian: Vulvo-vaginitis.

Notes, Short Comments, and Answers to Correspondents.

PUBLIC HEALTH AND THE PLUMBER: A NATIONAL APPRENTICESHIP SCHEME.

DURING April the Master, Wardens, and Court of the Plumbers' Company gave a luncheon at Carpenters' Hall to celebrate the inauguration of the new national scheme for apprenticeship in the plumbing trade. Apprenticeship as hitherto understood has practically died out in the South of England, while surviving in the North and Midlands, and a strong body of opinion now supports a scheme of far-reaching voluntary apprenticeship; such a scheme, brought forward by the united action of the Plumbers' Company, the Institute of Plumbers, and the United Operative Plumbers' and Domestic Engineers' Association, has been approved by the Board of Education, and Mr. H. A. L. Fisher, President of the Board, was amongst those gathered at the above-mentioned function to give the scheme a cordial send-off. The Plumbers' Company is the registration authority of the trade; since 1886 a system of voluntary registration has been maintained in order to ensure a high standard of workmanship and practice, and so secure and retain the confidence of health and water authorities, medical officers of health, architects, and engineers, and also to provide for better training by technical education adapted to new conditions. The Company has now pledged itself to compulsory registration if the latter can be obtained. The question of registration is, of course, intimately bound up with that of apprenticeship; the new scheme of indenture provides for the introduction of a fourth party, independent of the trade, whose function will be to hold the balance evenly between the other parties. No previous scheme of apprenticeship has had the hearty coöperation of all the bodies connected with the plumbing trade, and it is now felt that at last a real effort is being made to establish the trade on a scientific basis. Hitherto, it has been recognised, insufficient education has resulted in defects; from very early times (the first official record of the Company's existence dates from 1365) the plumber's responsibility has been recognised, and emphasised by exhortations to him "well and truly" to perform his work, together with statements of penalties attaching to scamped labour or dishonesty.

The science of public health demands the close coöperation of the plumber—drainage, lighting, and certain processes of commerce call for skill and exactitude on his part, and so little is known, even by medical men, of the details of the technique required in his work that cooperation is not so close as it ought to be. A recent publication on this subject, entitled "Domestic Sanitary Engineering and Plumbing," by F. W. Raynes (second edition. London: Longmans, Green, and Co., 1920, pp. 474, 21*s*.), written for students of domestic sanitary engineering and plumbing, and those entrusted with the design, supervision, and execution of this branch of engineering work, is particularly rich in illustrations and makes pleasant reading for the amateur. The chapters deal in a practical way with the various sanitary considerations required in building a house, and give information of much value to the medical practitioner. The plumber is a very necessary ally in any scheme for improvement in house construction, and no one interested in public health affairs can fail to approve of the new attempt to increase the usefulness of his ancient and important craft.

COCKROACHES: THEIR HISTORY AND CONTROL.

THE life-history and control of the cockroach are the subjects of a pamphlet recently issued by the British Museum (Natural History). The pamphlet (Economic Series, No. 12) is the work of Mr. Frederick Laing, M.A., B.Sc., Assistant in the Department of Entomology of the Museum; it contains a concise description of the common cockroach (*Blatta orientalis*) and the German cockroach (*Blattella germanica*), the two species of the insect which are found commonly in houses in this country. It is observed at the outset that the popular name of "black-beetle" is inaccurate; the cockroach is one of the Orthoptera, an order more primitive than the Coleoptera. The common and German cockroaches are neither of them indigenous in England, having apparently been introduced into the country by infested shipping, the former during the sixteenth century, the latter possibly about the time of the Crimean War.

Habits of the Cockroach.

The habits of the two species are very similar; their flattened bodies enable them to gain entrance through very small cracks and crevices, and to shelter almost anywhere. The neighbourhood of a kitchen range is, of course, their favourite spot; in certain parts of London the gas companies' men frequently find the space between the oven and the top of the gas-cooker filled with a thick mass of roasted cockroaches. Basements are particularly liable to be infested; heat, damp, and a good supply of food are essential for multiplication of the insects; nothing edible is refused by them—wall-paper, whitewash, books, boots, and hair are all devoured freely, but sweetened foods, and particularly beer, form the strongest attractions. The harm done is not so much the quantity eaten as the quantity spoilt; cockroaches leave their excreta over everything, and also communicate the peculiar "roachy" flavour to tainted food by means of a waxy secretion from certain glands, and by saliva ejected from the mouth. Infestation of dwelling-houses takes place by the introduction of furniture, groceries, linen, &c., from sources already infested. Hotels and restaurants are frequently centres of dissemination. The two species of cockroach are very rarely found together; *Blatta orientalis* is the dominant species in this country, but when *Blattella germanica* occurs it is usually found in very large numbers, owing to its greater rapidity in breeding. The cockroach is normally a scavenger, and may sometimes be useful in removing dead animal matter. It also preys upon, and finally eradicates, the bed-bug—an advantage which in England does not countervail the unpleasantness of its own presence.

The Common Cockroach.—German, American, and Australian Cockroaches.

The sexes of the common cockroach differ markedly in appearance; the elytra and wings are strongly developed in the male, but rudimentary in the female; neither is black in colour, but a very dark brown. The antennæ are nearly as long as the body, and composed of many segments; they are liable to get broken, but like many other insects the cockroach has the power of regenerating lost parts provided the final adult stage of growth has not been reached, and provided a stump of the damaged organ remains. The cockroach grows in stages terminated by moults (of which the number and periodicity are not accurately known, partly because the insect eats its cast cuticle) and if injured the antennæ—or leg, as the case may be—never assume a perfect form at the next moult. The female of the common cockroach preponderates over the male in a proportion of about 3 to 1. Paring is confined to certain months—probably from April to September—and oviposition begins about a week after pairing; the eggs are laid in a capsule, arranged in two rows of about eight eggs each, and the female may carry the capsule protruding from the extremity of the abdomen for from 12 hours to four or five days, at the end of which time she deposits it in a warm sheltered spot, preferably near a food-supply. Normal hatching probably occurs within a few days; the capsule splits and the larvæ emerge to fend for themselves, as the mother takes no interest in her progeny. Each female is capable of laying a number of capsules—experiments have shown an average of eight, from each of which an average of ten larvæ were hatched; an immediate progeny of 80 may thus derive from one insect.

The German cockroach is dark yellow or light brown in colour, being only about half the size of the common species. Both sexes have fully developed wings; the proportion of females to males is apparently about 9 to 1, and pairing occurs at any time during the year. The female is sometimes said to be capable of laying only one capsule, but it is also held that two at least may be laid. *Blattella germanica*, unlike *Blatta orientalis*, assists her young to hatch. The American cockroach (*Periplaneta americana*) and the Australian cockroach (*Periplaneta australasiæ*) are not often found in dwelling-houses in this country. The former is the largest of our domestic species, reaching a length of about 35 mm.; it is mainly confined to warehouses, breweries, sugar-refineries, &c. The Australian species is similar but smaller, and is chiefly met with in glass-houses and forcing-pits, where it may do much damage by nibbling at plants, being more of a vegetarian and less of a scavenger than the other three varieties.

Cockroaches and Disease.—Methods of Control.

Cockroaches have not as yet been convicted of transmitting disease to human beings, although several attempts have been made to connect them with the dissemination of cancer. In one of these attempts[1] it was alleged that a worm in the rat passed its larval stage in the intestine of the cockroach; the rat ate the cockroach and became infested with the worm, which caused tumours found, on examination of the rat, to be of a cancerous nature. But there is as yet no very substantial evidence to go upon; the most that can be said is that the presence of the cockroach is unpleasant and its habits destructive.

To rid the house of these insects special attention should be paid to brick and tile work around fireplaces, to skirting-boards and cupboards, and to the entrances of gas- and water-pipes. The pamphlet advises cementing up of all crevices, and various insect powders are recommended for use afterwards. Of these a mixture of sodium fluoride and pyrethrum powder (in a proportion of 3 to 1) has been found very satisfactory and is harmless to pet animals. Powdered borax, sweetened or mixed with pyrethrum powder, and the well-known remedy of a mixture of one part of plaster-of-Paris with two parts of sugar, are also efficacious. Phosphorus paste is useful, but dangerous to other animals. Traps are to be bought or are easily made; stale beer and peeled bananas make the best bait. Sulphur dioxide, generated by burning brimstone, is the most efficient and least dangerous gas for fumigation; carbon bisulphide is useful, but very easily ignited, even from a distance. In places where heat can be applied a temperature of 130° F. can be relied upon to give good results, if maintained long enough to penetrate the lairs of the insects.

BLIND GARDENERS.

THE inaugural meeting of the Guild of Blind Gardeners is to be held on May 26th at the National Library for the Blind, 18, Tufton-street, Westminster, S.W. A suggestion to train the blind for land work was brought before the Ophthalmological Congress at Oxford in July, 1919; the committee appointed by the Council of the Congress has endorsed the draft scheme drawn up by Mrs. Adolphus Duncombe for the establishment of a school of gardening and farming for the blind, to which school ophthalmic surgeons can recommend their patients to go for necessary training. The object of the Guild is to encourage the blind to take up gardening as a healthy and interesting occupation, either as a means of earning a livelihood or in addition to any sedentary work in which they may already be engaged. The funds will be for the advancement of this object; it is hoped to raise sufficient to offer a scholarship to a man or woman who attains to a certain standard of knowledge in cultivation and manipulation of plants. At present no works on gardening exist in Braile; the National Library for the Blind is now engaged in the preparation of suitable books and pamphlets to assist blind students in their technical education.

Given the taste and aptitude for gardening it is hard to conceive a happier occupation for those handicapped by loss of sight. It is quite clear that the material benefit to be gained cannot be great; the blind man must work slowly, and State or philanthropic aid must be invoked to protect him from the necessity of competing in the market for his living. But the physical benefit of such work may be very great, and its psychological value to the individual, its opportunities for self-expression and intellectual development, will be enormous.

GOATS' MILK.

IN the Year Book for 1921, issued by the British Goat Society, Mr. F. J. Lloyd, F.I.C., F.C.S., has an informing paper on goats' milk, in which he marshals some of the main facts already known about it, and calls attention to various related points on which further research is desirable. It is pointed out that any attempt to appraise the milk of an animal must obviously take cognizance of quantity as well as of quality, and in both these respects the goat varies a good deal, the quantity yielded ranging from 1 to 10 lb. a day, with 5 lb. as a fair average, the quality, especially as regards the fat content, varying quite as widely. The figures given for the 1920 Dairy Show indicate a fat variation from 2·17 to 9·53 per cent., the average being under 5 per cent.; and although this marks a distinct advance on the results obtained in previous years the author is emphatically of the opinion that there is still room for improvement, and that the first desideratum is to obtain a more uniform standard in the produce of the goat. The suggestion is made that the fluctuations in quality observed depend not so much on the exceptional circumstances, which are often the causes of an abnormal milk yield in cows, as upon the fact that there are probably a far greater number of goats which naturally yield milk of poor quality than owners and breeders of goats realise. The remedy both for deficient quality and quantity is therefore careful selective breeding, with the elimination of animals yielding milk of an inferior quality, rather than an attempt at improvement by means of drugs or special feeding. Mr. Lloyd believes, however, that the amount of casein, and probably of albumin also, in goats' milk—both of which constituents are present in much greater amount than in cows' milk—depends on the presence of lime in the food; in this respect his conclusions coincide with those of Fingerling, who found that in goats fed on a diet deficient in calcium and phosphorus a fall occurred both in the amount of constituents and of the total milk secreted; both of these returned to the normal on restoring the calcium and phosphates to the diet. One point raised upon which further information is desirable, and could easily be obtained, is whether or not the fat content of goats' milk diminishes with prolonged milking, as one investigator has stated to be the case. Other points requiring elucidation are the degree of relationship, if any, between the phosphoric acid and the casein present, as well as between the calcium and the casein. With regard to the question of tuberculous infection in goats, the general opinion seems to be that the disease, if it occurs at all in this animal, is relatively rare; and Mr. Lloyd suggests that this comparative immunity may be due to the presence in the goat of an antitoxin to tuberculosis, seeing in this a rational basis for the old and widespread belief in the efficacy of goats' milk as a food for tuberculous patients. There exists undoubtedly a field for useful research in this direction, as also for the determination, quantitatively and qualitatively, of the vitamin content. Mr. Lloyd remarks truly that until recently chemical analysis has possibly concerned itself overmuch with the gross constituents of food materials at the expense of those substances to which, in spite of the minute quantities in which they are present, the main virtue of those food materials may be due.

APPROVED SALVARSAN SUBSTITUTES.

LOCAL authorities are authorised to supply, free of charge to medical practitioners, only those substitutes for salvarsan and neo-salvarsan which have received the approval of the Ministry of Health. In the most recent list (Circular 166) the approved drugs are given as follows:—

Arsenobillon (May and Baker) in doses of 0·1–0·6 g. (costing 1*s.* to 5*s.*). Novarsenobillon (May and Baker) in doses of 0·15–0·9 g. (costing 9*d.* to 4*s.* 6*d.*).

Diarsenol (Allen and Hanburys) in doses of 0·1–3 g. (costing 1*s.* to 22*s.*). Neodiarsenol (Allen and Hanburys) in doses of 0·15–4·5 g. (costing 9*d.* to 21*s.*).

Galyl (Anglo-French Drug Company) in doses of 0·1–0·4 g., dilute (costing 2*s.* to 5*s.* 6*d.*) or concentrated for intramuscular use (costing 2*s.* 6*d.* to 6*s.*).

Kharsivan (Burroughs, Wellcome) in doses of 0·1–0·6 g. (costing 1*s.* to 5*s.*). Neokharsivan (Burroughs, Wellcome) in doses of 0·15–0·9 g. (costing 9*d.* to 4*s.* 6*d.*).

Salvarsan (Evans, Sons, Lescher, and Webb) in doses of 0·1–3 g. (costing 1*s.* to 25*s.*).

The grant in aid of expenditure incurred by local authorities in the purchase of these drugs is based on the prices specified.

THE VALUE OF ALLOTMENTS: THE KING'S LEAD.

IN THE LANCET of Feb. 15th, 1919, we expressed the hope that allotments, which the war had made a national necessity, should remain a permanent feature of English life. Social unrest, with a consequent lowering of productive efficiency, as well as the vagaries of the weather (the late frosts have damaged the potato crops in various parts of the country), still enforce the need for encouraging allotment culture, and it is in keeping with His Majesty's interest in the welfare of his subjects that he should recognise this need. After the armistice the residents of Hampton Wick and Teddington had their allotments in Bushy Park taken from them. They appealed to the Master of the Horse for the King's permission to use one of the paddocks in the park for the cultivation of vegetables, and their request has been granted. The benefits of allotments to the community are of far-reaching good from whatever point of view they may be regarded—economical, physical, mental, or moral. From the health point of view, with which we are mainly concerned, there can be no doubt that fresh vigour has been given to the town dweller, who not only finds healthy recreation in cultivating his plot after the sedentary occupations of the day, but finds also in digging the necessary physical exercise which otherwise he probably would not obtain. The incentive to early rising, the enforced intake of fresh air, and the change of mental attitude are other factors in the management of an allotment which must conduce to health.

DATE OF THE INTRODUCTION OF ANÆSTHESIA.

IN a recent letter to the *Journal of the American Medical Association* the veteran Prof. W. W. Keen, of Philadelphia, pointed out that the article Anæsthesia in the "Encyclopædia Britannica" is incomplete as regards details given of the introduction of the process. He quotes the "Ether Day" address given by Professor W. H. Welch, of Johns Hopkins University, on Oct. 16th, 1908, to show that it was the operation (dissecting out of a tumour from the neck of one Gilbert Abbott) performed under surgical anæsthesia by Dr. John C. Warren at the Massachusetts General Hospital on Oct. 16th, 1846, in the presence of the Harvard medical students and of a number of distinguished medical men, which first demonstrated to the world at large the value of the method. The "Encyclopædia Britannica" gives Sept. 30th of the same year as the date of introduction; on that day Dr. W. T. G. Morton, a dentist of Boston, used ether to induce general anæsthesia for the purpose of extracting a tooth. This operation was done in private in Dr. Morton's office, and Dr. Morton himself is quoted[1] as referring to Warren's operation in these words: "This I consider to be the first demonstration of this new fact in science."

ASTHMA.

LIBRARY

Delivered before the Chichester and Worthing Division of the British Medical Association on Feb. 16th, 1921,

BY ARTHUR F. HURST, M.A., M.D. OXON.,
F.R.C.P. LOND.,

PHYSICIAN AND NEUROLOGIST TO GUY'S HOSPITAL.

LIKE Sir John Floyer, who published the first book in the English language on asthma in 1698, I myself suffer from asthma, so I have the advantage, which few writers on the subject possess, of 27 years of observation on my own corpus vile. The subject is one of special interest at present, as recent research in England, America, and France, has led to the explanation of many problems connected with asthma which had previously been obscure.

DEFINITION.

I would define asthma as the reaction of an over-excitable bronchial centre to blood-borne irritants and to peripheral and psychical stimuli. One part of the vagal nucleus in the medulla controls the activity of the bronchi. Normally it is in a certain degree of tonic activity. When over-active the broncho-motor fibres of the vagus cause the bronchioles to contract and the broncho-secretory fibres cause the secretion of bronchial mucus to be excessive. This general over-activity is associated with congestion of the bronchial mucous membrane, analogous to what occurs in all other organs when in a condition of functional activity. The engorged mucous membrane adds to the bronchial obstruction caused by the spasm of the circular muscle fibres, and consequently the mucus cannot be easily expelled. It is retained so long that it undergoes a process of coagulation, similar to the change which occurs in the formation of fibrin from fibrinogen, this being due to the activity of a ferment, mucinase, which is present in the bronchial mucous membrane. As the coagulated mucous casts of the bronchioles are slowly expelled along the spiral bronchi they assume the characteristic features of the spiral mucous filaments described by Curschmann, of Leipzig, in 1883. An exactly similar process occurs in the bowel in mucomembranous colitis; mucus is secreted in excess, and owing to the associated spasm it is retained abnormally long, so that there is time for the characteristic membrane to form as a result of the action of the mucinase of the intestinal mucous membrane.

ASTHMA AND ANAPHYLAXIS.

Our knowledge of the blood-borne irritants of the bronchial centre is of recent origin, and my own interest in the subject was stimulated by a visit to America in the summer of 1919. Much important work on the subject has been carried out by Freeman,[1] of St. Mary's, and Walker,[2] of Harvard, work which has thrown light on the hitherto inexplicable individual variations in the ætiology of asthma.* The irritant is generally, but not always, a protein to which the individual is abnormally sensitive. The nature of these toxic idiopathies, as they have been called by Freeman, is obscure, but they present many analogies to experimental anaphylaxis, and it appears probable that they are really examples of anaphylaxis occurring in man owing to inherited or acquired sensitiveness to certain proteins. In guinea-pigs bronchial spasm is one of the characteristic phenomena of anaphylaxis. Whether a man who is sensitive to a certain protein will be unaffected by exposure to a moderate dose of it, or whether he will develop asthma, an urticarial or eczematous rash, or an acute gastro-intestinal attack, depends upon whether he has an irritable bronchial centre, an irritable skin, or an irritable digestive tract.

Walker found that in 52 per cent. of 400 cases of asthma the patient was specifically sensitive to one or more of his available proteins, as shown by the cutaneous tests, and that desensitisation generally prevented the development of asthma, whereas subcutaneous injection of the specific protein produced an attack of asthma. I believe that a still larger proportion of patients would give a positive reaction if they were tested whilst actually asthmatic, as the degree of sensibility varies with the state of the patient's general health, and he may fail to react to proteins during a period of freedom from attacks, although the same proteins may produce well-marked reactions during an asthmatic period.

The protein may gain access to the body by inhalation in the case of pollen, emanations from the hair and skin of animals, and the dust of cereal grains; it is ingested in the case of a great variety of foods; and, lastly, the protein may be derived from bacteria which have formed a focus of infection in the bronchi or less frequently the tonsils, nose, teeth, or intestines. The anaphylactic factor is most common in cases beginning in early life; thus 80 per cent. of those beginning in the first 2 years of life, 65 per cent. from 2 to 15, 50 per cent. from 15 to 35, 25 per cent. from 35 to 50, and none beginning after 50 were of this type (Walker). The special liability in children is most marked with food proteins, and next with animal proteins; the liability to bacterial proteins is equally distributed whatever is the age of onset up to 40.

Food.

Goodale[3] in 1916 showed that extracts of wheat foods gave positive skin reactions in asthmatics who had attacks of asthma when they ate bread. Walker has more recently investigated the question in connexion with a great variety of foods. In 68 out of his 400 cases the patient was sensitive to food protein. In more than half of them (35) the protein was derived from cereals, in most instances wheat (25), but occasionally maize (6), rice (3), rye (2), barley or oats, and sometimes from several sources in the same individual. Maize, oat, rye, and barley rarely caused symptoms before the war, as until the introduction of war bread few people ate enough of them to have any effect. Wodehouse has shown that different individuals are sensitive to different wheat proteins. In most cases the natural proteose of wheat is the most active and differs from the proteose produced artificially from the gluten of wheat. Heating, except to very high temperatures, does not affect the anaphylactogenic properties of wheat proteins.

Next to cereals come eggs among the foods which may cause asthma, and then potato, casein, and fish, especially lobster, oyster, salmon, mackerel, cod, and haddock. The proteins of beef, chicken, and other forms of meat, spinach and other vegetables, strawberries and other fruit are occasionally active, but generally in association with other food proteins. There are, indeed, few if any foods to which some individuals are not sensitive.

Only a small proportion of patients discover for themselves that the particular article of diet to which they are shown to be sensitive by the skin reaction gives them asthma, and in some cases eczema and urticaria as well. They have sometimes, however, a distaste for the food to which they are sensitive, especially in the case of eggs.

Pollen.

Freeman has found as the result of the long series of investigations on hay fever he has carried out during the last ten years that, although a patient suffering from hay fever or hay asthma may be use afterwards. Of these a mixture of sodium fluoride and pyrethrum powder (in a proportion of 3 to 1) has been found very satisfactory and is harmless to pet animals. Powdered borax, sweetened or mixed with pyrethrum powder, and the well-known remedy of a mixture of one part of plaster-of-Paris with two parts of sugar, are also efficacious. Phosphorus paste is useful, but dangerous to other animals. Traps are to be bought or are easily made; stale beer and peeled bananas make the best bait. Sulphur dioxide, generated by burning brimstone, is the most efficient and least dangerous gas for fumigation; carbon bisulphide is useful, but very easily ignited, even from a distance. In places where heat can be applied a temperature of 130° F. can be relied upon to give good results, if maintained long enough to penetrate the lairs of the insects.

---

* Frank Coke's important investigations on the subject were published some weeks after the delivery of this lecture. Brit. Med. Jour., March 12th, 1921.

BLIND GARDENERS.

THE inaugural meeting of the Guild of Blind Gardeners is to be held on May 26th at the National Library for the Blind, 18, Tufton-street, Westminster, S.W. A suggestion to train the blind for land work was brought before the Ophthalmological Congress at Oxford in July, 1919; the committee appointed by the Council of the Congress has endorsed the draft scheme drawn up by Mrs. Adolphus Duncombe for the establishment of a school of gardening and farming for the blind, to which school ophthalmic surgeons can recommend their patients to go for necessary training. The object of the Guild is to encourage the blind to take up gardening as a healthy and interesting occupation, either as a means of earning a livelihood or in addition to any sedentary work in which they may already be engaged. The funds will be for the advancement of this object; it is hoped to raise sufficient to offer a scholarship to a man or woman who attains to a certain standard of knowledge in cultivation and manipulation of plants. At present no works on gardening exist in Braile; the National Library for the Blind is now engaged in the preparation of suitable books and pamphlets to assist blind students in their technical education.

Given the taste and aptitude for gardening it is hard to conceive a happier occupation for those handicapped by loss of sight. It is quite clear that the material benefit to be gained cannot be great; the blind man must work slowly, and State or philanthropic aid must be invoked to protect him from the necessity of competing in the market for his living. But the physical benefit of such work may be very great, and its psychological value to the individual, its opportunities for self-expression and intellectual development, will be enormous.

GOATS' MILK.

IN the Year Book for 1921, issued by the British Goat Society, Mr. F. J. Lloyd, F.I.C., F.C.S., has an informing paper on goats' milk, in which he marshals some of the main facts already known about it, and calls attention to various related points on which further research is desirable. It is pointed out that any attempt to appraise the milk of an animal must obviously take cognizance of quantity as well as of quality, and in both these respects the goat varies a good deal, the quantity yielded ranging from 1 to 10 lb. a day, with 5 lb. as a fair average, the quality, especially as regards the fat content, varying quite as widely. The figures given for the 1920 Dairy Show indicate a fat variation from 2·17 to 9·53 per cent., the average being under 5 per cent.; and although this marks a distinct advance on the results obtained in previous years the author is emphatically of the opinion that there is still room for improvement, and that the first desideratum is to obtain a more uniform standard in the produce of the goat. The suggestion is made that the fluctuations in quality observed depend not so much on the exceptional circumstances, which are often the causes of an abnormal milk yield in cows, as upon the fact that there are probably a far greater number of goats which naturally yield milk of poor quality than owners and breeders of goats realise. The remedy both for deficient quality and quantity is therefore careful selective breeding, with the elimination of animals yielding milk of an inferior quality, rather than an attempt at improvement by means of drugs or special feeding. Mr. Lloyd believes, however, that the amount of casein, and probably of albumin also, in goats' milk—both of which constituents are present in much greater amount than in cows' milk—depends on the presence of lime in the food; in this respect his conclusions coincide with those of Fingerling, who found that in goats fed on a diet deficient in calcium and phosphorus a fall occurred both in the amount of constituents and of the total milk secreted; both of these returned to the normal on restoring the calcium and phosphates to the diet. One point raised upon which further information is desirable, and could easily be obtained, is whether or not the fat content of goats' milk diminishes with prolonged milking, as one investigator has stated to be the case. Other points requiring elucidation are the degree of relationship, if any, between the phosphoric acid and the casein present, as well as between the calcium and the casein.

With regard to the question of tuberculous infection in goats, the general opinion seems to be that the disease, if it occurs at all in this animal, is relatively rare; and Mr. Lloyd suggests that this comparative immunity may be due to the presence in the goat of an antitoxin to tuberculosis, seeing in this a rational basis for the old and widespread belief in the efficacy of goats' milk as a food for tuberculous patients. There exists undoubtedly a field for useful research in this direction, as also for the determination, quantitatively and qualitatively, of the vitamin content. Mr. Lloyd remarks truly that until recently chemical analysis has possibly concerned itself overmuch with the gross constituents of food materials at the expense of those substances to which, in spite of the minute quantities in which they are present, the main virtue of those food materials may be due.

APPROVED SALVARSAN SUBSTITUTES.

LOCAL authorities are authorised to supply, free of charge to medical practitioners, only those substitutes for salvarsan and neo-salvarsan which have received the approval of the Ministry of Health. In the most recent list (Circular 166) the approved drugs are given as follows:—

Arsenobillon (May and Baker) in doses of 0·1-0·6 g. (costing 1*s.* to 5*s.*). Novarsenobillon (May and Baker) in doses of 0·15-0·9 g. (costing 9*d.* to 4*s.* 6*d.*).

Diarsenol (Allen and Hanburys) in doses of 0·1-3 g. (costing 1*s.* to 22*s.*). Neodiarsenol (Allen and Hanburys) in doses of 0·15-4·5 g. (costing 9*d.* to 21*s.*).

Galyl (Anglo-French Drug Company) in doses of 0·1-0·4 g., dilute (costing 2*s.* to 5*s.* 6*d.*) or concentrated for intramuscular use (costing 2*s.* 6*d.* to 6*s.*).

Kharsivan (Burroughs, Wellcome) in doses of 0·1-0·6 g. (costing 1*s.* to 5*s.*). Neokharsivan (Burroughs, Wellcome) in doses of 0·15-0·9 g. (costing 9*d.* to 4*s.* 6*d.*).

Salvarsan (Evans, Sons, Lescher, and Webb) in doses of 0·1-3 g. (costing 1*s.* to 25*s.*).

The grant in aid of expenditure incurred by local authorities in the purchase of these drugs is based on the prices specified.

THE VALUE OF ALLOTMENTS: THE KING'S LEAD.

IN THE LANCET of Feb. 15th, 1919, we expressed the hope that allotments, which the war had made a national necessity, should remain a permanent feature of English life. Social unrest, with a consequent lowering of productive efficiency, as well as the vagaries of the weather (the late frosts have damaged the potato crops in various parts of the country), still enforce the need for encouraging allotment culture, and it is in keeping with His Majesty's interest in the welfare of his subjects that he should recognise this need. After the armistice the residents of Hampton Wick and Teddington had their allotments in Bushy Park taken from them. They appealed to the Master of the Horse for the King's permission to use one of the paddocks in the park for the cultivation of vegetables, and their request has been granted. The benefits of allotments to the community are of far-reaching good from whatever point of view they may be regarded—economical, physical, mental, or moral. From the health point of view, with which we are mainly concerned, there can be no doubt that fresh vigour has been given to the town dweller, who not only finds healthy recreation in cultivating his plot after the sedentary occupations of the day, but finds also in digging the necessary physical exercise which otherwise he probably would not obtain. The incentive to early rising, the enforced intake of fresh air, and the change of mental attitude are other factors in the management of an allotment which must conduce to health.

DATE OF THE INTRODUCTION OF ANÆSTHESIA.

IN a recent letter to the *Journal of the American Medical Association* the veteran Prof. W. W. Keen, of Philadelphia, pointed out that the article Anæsthesia in the "Encyclopædia Britannica" is incomplete as regards details given of the introduction of the process. He quotes the "Ether Day" address given by Professor W. H. Welch, of Johns Hopkins University, on Oct. 16th, 1908, to show that it was the operation (dissecting out of a tumour from the neck of one Gilbert Abbott) performed under surgical anæsthesia by Dr. John C. Warren at the Massachusetts General Hospital on Oct. 16th, 1846, in the presence of the Harvard medical students and of a number of distinguished medical men, which first demonstrated to the world at large the value of the method. The "Encyclopædia Britannica" gives Sept. 30th of the same year as the date of introduction; on that day Dr. W. T. G. Morton, a dentist of Boston, used ether to induce general anæsthesia for the purpose of extracting a tooth. This operation was done in private in Dr. Morton's office, and Dr. Morton himself is quoted[1] as referring to Warren's operation in these words: "This I consider to be the first demonstration of this new fact in science."

[illegible]

LIBR

Delivered before the Chichester and Worthing Division of the British Medical Association on Feb. 16th, 1921,

BY ARTHUR F. HURST, M.A., M.D. OXON., F.R.C.P. LOND.,
PHYSICIAN AND NEUROLOGIST TO GUY'S HOSPITAL.

LIKE Sir John Floyer, who published the first book in the English language on asthma in 1698, I myself suffer from asthma, so I have the advantage, which few writers on the subject possess, of 27 years of observation on my own corpus vile. The subject is one of special interest at present, as recent research in England, America, and France, has led to the explanation of many problems connected with asthma which had previously been obscure.

DEFINITION.

I would define asthma as the reaction of an over-excitable bronchial centre to blood-borne irritants and to peripheral and psychical stimuli. One part of the vagal nucleus in the medulla controls the activity of the bronchi. Normally it is in a certain degree of tonic activity. When over-active the broncho-motor fibres of the vagus cause the bronchioles to contract and the broncho-secretory fibres cause the secretion of bronchial mucus to be excessive. This general over-activity is associated with congestion of the bronchial mucous membrane, analogous to what occurs in all other organs when in a condition of functional activity. The engorged mucous membrane adds to the bronchial obstruction caused by the spasm of the circular muscle fibres, and consequently the mucus cannot be easily expelled. It is retained so long that it undergoes a process of coagulation, similar to the change which occurs in the formation of fibrin from fibrinogen, this being due to the activity of a ferment, mucinase, which is present in the bronchial mucous membrane. As the coagulated mucous casts of the bronchioles are slowly expelled along the spiral bronchi they assume the characteristic features of the spiral mucous filaments described by Curschmann, of Leipzig, in 1883. An exactly similar process occurs in the bowel in muco-membranous colitis; mucus is secreted in excess, and owing to the associated spasm it is retained abnormally long, so that there is time for the characteristic membrane to form as a result of the action of the mucinase of the intestinal mucous membrane

ASTHMA AND ANAPHYLAXIS.

Our knowledge of the blood-borne irritants of the bronchial centre is of recent origin, and my own interest in the subject was stimulated by a visit to America in the summer of 1919. Much important work on the subject has been carried out by Freeman,[1] of St. Mary's, and Walker,[2] of Harvard, work which has thrown light on the hitherto inexplicable individual variations in the ætiology of asthma.* The irritant is generally, but not always, a protein to which the individual is abnormally sensitive. The nature of these toxic idiopathies, as they have been called by Freeman, is obscure, but they present many analogies to experimental anaphylaxis, and it appears probable that they are really examples of anaphylaxis occurring in man owing to inherited or acquired sensitiveness to certain proteins. In guinea-pigs bronchial spasm is one of the characteristic phenomena of anaphylaxis. Whether a man who is sensitive to a certain protein will be unaffected by exposure to a moderate dose of it, or whether he will develop asthma, an urticarial or eczematous rash, or an acute gastro-intestinal attack, depends upon whether he has an irritable bronchial centre, an irritable skin, or an irritable digestive tract.

Walker found that in 52 per cent. of 400 cases of asthma the patient was specifically sensitive to one or more of his available proteins, as shown by the cutaneous tests, and that desensitisation generally prevented the development of asthma, whereas subcutaneous injection of the specific protein produced an attack of asthma. I believe that a still larger proportion of patients would give a positive reaction if they were tested whilst actually asthmatic, as the degree of sensibility varies with the state of the patient's general health, and he may fail to react to proteins during a period of freedom from attacks, although the same proteins may produce well-marked reactions during an asthmatic period.

The protein may gain access to the body by inhalation in the case of pollen, emanations from the hair and skin of animals, and the dust of cereal grains; it is ingested in the case of a great variety of foods; and, lastly, the protein may be derived from bacteria which have formed a focus of infection in the bronchi or less frequently the tonsils, nose, teeth, or intestines. The anaphylactic factor is most common in cases beginning in early life; thus 80 per cent. of those beginning in the first 2 years of life, 65 per cent. from 2 to 15, 50 per cent. from 15 to 35, 25 per cent. from 35 to 50, and none beginning after 50 were of this type (Walker). The special liability in children is most marked with food proteins, and next with animal proteins; the liability to bacterial proteins is equally distributed whatever is the age of onset up to 40.

Food.

Goodale[3] in 1916 showed that extracts of wheat foods gave positive skin reactions in asthmatics who had attacks of asthma when they ate bread. Walker has more recently investigated the question in connexion with a great variety of foods. In 68 out of his 400 cases the patient was sensitive to food protein. In more than half of them (35) the protein was derived from cereals, in most instances wheat (25), but occasionally maize (6), rice (3), rye (2), barley or oats, and sometimes from several sources in the same individual. Maize, oat, rye, and barley rarely caused symptoms before the war, as until the introduction of war bread few people ate enough of them to have any effect. Wodehouse has shown that different individuals are sensitive to different wheat proteins. In most cases the natural proteose of wheat is the most active and differs from the proteose produced artificially from the gluten of wheat. Heating, except to very high temperatures, does not affect the anaphylactogenic properties of wheat proteins.

Next to cereals come eggs among the foods which may cause asthma, and then potato, casein, and fish, especially lobster, oyster, salmon, mackerel, cod, and haddock. The proteins of beef, chicken, and other forms of meat, spinach and other vegetables, strawberries and other fruit are occasionally active, but generally in association with other food proteins. There are, indeed, few if any foods to which some individuals are not sensitive.

Only a small proportion of patients discover for themselves that the particular article of diet to which they are shown to be sensitive by the skin reaction gives them asthma, and in some cases eczema and urticaria as well. They have sometimes, however, a distaste for the food to which they are sensitive, especially in the case of eggs.

Pollen.

Freeman has found as the result of the long series of investigations on hay fever he has carried out during the last ten years that, although a patient suffering from hay fever or hay asthma may be shown experimentally to be sensitive to a variety of pollens, grass pollen is the only one of any importance in England. It is always present in the air during the grass-flowering season, from the middle of May to the beginning of August, except when recent rain has washed it away. It alone of English pollens is produced in sufficient amount, and is sufficiently easily disseminated by light wind, and is capable of producing a strong reaction. Daisy pollen, for example, only flies a few yards in contrast to grass pollen which can fly many miles, and trees only pollinate for a few days instead of for several weeks. In America conditions are very different, and Walker has shown the need for investigating the sensitiveness of each patient to a large variety of pollens. The majority of cases of hay asthma are associated with hay fever, which occurs, of course, still more frequently as an independent condition.

---

* Frank Coke's important investigations on the subject were published some weeks after the delivery of this lecture. Brit. Med. Jour., March 12th, 1921.

Animal Emanations.

Hyde Salter[4] was the first to recognise that asthma may be caused by the emanation from animals. In 1859 he noted cases of asthma brought on by the presence of cats, horses, guinea-pigs, rabbits, hares, cattle, sheep, and deer. Cat and horse asthma are the most common, the others being comparatively rare. Many patients are at once aware of the presence of a cat in the room from the development of asthmatic symptoms, which are sometimes associated with nasal catarrh and even urticaria. Trousseau described a case of a woman who had an attack of asthma directly her feather-bed was shaken in her presence, and Salter had a patient who could not sleep upon a pillow stuffed with feathers. Freeman writes of a patient who said, "You must put your head on the pillow as upon a wasp's nest." Goodale in 1916 found that an alcoholic extract of the hair of cats produced a skin reaction in patients suffering from cat asthma, the reaction apparently indicating that the individual was anaphylactic to the proteins contained in the extract. Wodehouse[5] found that the substance in the hair of cats and other animals which gave rise to the reaction was not the keratin, which forms the main constituent of hair, nor the proteins of their blood, but various other proteins which he isolated from the dandruff of the animal's skin. Freeman has shown that a slighter reaction is also produced by the flesh, serum, fæces, and nasal mucus in individuals who are sensitive to the dandruff, and that sensitiveness to a horse is associated with a lesser degree of sensitiveness to other members of the horse-tribe, such as the zebra, but to a very slight extent, as a rule, to the donkey.

The quantity of specific protein required to cause an attack of asthma is, of course, exceedingly minute. The comparatively large quantity of foreign protein introduced into the circulation when horse serum is used therapeutically is sufficient to produce an attack in many asthmatics who are not otherwise liable to horse asthma. Anti-diphtheritic or other serum ought, therefore, never to be given to an asthmatic without preliminary desensitisation. In the absence of this precaution death from anaphylactic shock has occurred in a number of cases described by Collier, of Oxford, and others.

Bacterial Toxins.

It has long been recognised that asthma may be associated with infection of the bronchi, and less commonly of the teeth, nasal mucous membrane, tonsils, and intestines. The infection may give rise to the production of bacterial proteins to which the individual is abnormally sensitive, in which case the asthma is of anaphylactic origin, or the lesion produced may act as an irritant focus and give rise to reflex attacks of asthma. It is possible to distinguish between these two possibilities by testing the cutaneous reaction to the toxins of each organism isolated from the sputum or other infective material or to stock toxins obtained from various organisms; a positive reaction is obtained in the anaph but not in the reflex cases. Vaccination ma to improvement in both classes, but this is lik be more marked in the former. Dr. John tells me that the organism which most frequentl a specific relation with asthma is a bacillus o Friedländer group; this is often found in the sp coughed up during an attack.

Other Proteins.

Asthmatics are occasionally sensitive to ot proteins as well as those already referred to. Th in one of Walker's patients an attack was alwa produced in the presence of a flax-seed poultice, an in another the attacks were caused by tobacc smoke, as in a case described by Floyer in 1726. The patients were found by the skin reaction to be sensitive to a protein in flax-seed and tobacco respectively. In a third case a jewel polisher was found to be sensitive to protein obtained from the dust of the boxwood he used in his work. Sensitisation of this kind undoubtedly explains many of the remarkable idiosyncrasies shown by asthmatics.

Multiple Sensitisation.

Walker found that multiple sensitisation was uncommon in cases which begin later than the age of 10, but it is common if it begins in infancy. It is probable that sensitisation to one protein early in life tends to be followed by subsequent sensitisation to others. Skin reactions indicating multiple sensitisation do not necessarily indicate that the asthma is at the actual moment being produced by all the proteins, although each is a potential cause and requires separate consideration in determining what treatment should be undertaken.

REFLEX CAUSES.

The most important peripheral stimuli which may affect an irritable bronchial centre and produce asthma reflexly arise in the nose, bronchi, stomach, and bowel. There is a point on the mucous membrane of the nasal septum opposite the inferior turbinal which appears to be specially rich in afferent nerve fibres which may influence the bronchial centre. Touching this with a probe may cause an asthmatic patient to wheeze, and contact with a congested inferior turbinal may give rise to an attack of asthma. Congestion of the turbinal is most frequently caused by infection, but apart from this contact may occur in individuals with a narrow nose or deflected septum, especially when the turbinal swells as a result of gravity on assuming the horizontal position, this being one reason why sleep is much less likely to be interrupted by an attack of asthma if the patient sits in a chair instead of going to bed.

I have already pointed out that the association of bronchial infection with asthma is due to either or both of two factors—sensitiveness to the toxin of one or more of the infecting organisms, and a reflex caused by the irritation of the bronchial mucous membrane by the infection; the latter must be present alone when the cutaneous reactions are absent. but improvement results from vaccination. Distension of the stomach with food may cause asthma, especially in the evening, quite independently of the nature of the food. Similarly distension of the rectum with fæces produces reflex asthma in patients with an irritable bronchial centre immediate relief follows defæcation.

HYSTERICAL AND EMOTIONAL ASTHMA.

In an individual with an irritable bronchial centre, but never apart from this, asthma may be caused by an idea or an emotion. Thus if a patient has had an attack under certain conditions he will expect to have another if the conditions are repeated. When for any reason the conditions have altered, but without the patient's knowledge, he may yet be so convinced that an attack will occur that one is produced. Asthma caused by auto-suggestion in this way is truly hysterical, though in the absence of an abnormal bronchial centre no amount of suggestion could cause bronchial spasm and hypersecretion. Trousseau describes the case of a lady, who always had asthma in the presence of roses and had an attack when she saw some artificial roses which she thought were real. On my first visit to Salisbury in 1908 I had a very severe attack, which was repeated the following year, but I had no further attacks on numerous occasions in 1918 and 1919 when I revisited the city, as I had meanwhile become firmly convinced that my second attack was brought on solely by expectation, whatever may have been the cause of the first. Many patients who learn to rely on certain remedies are sure to become asthmatic if they discover that they have forgotten to take their powder, inhalation, or injection with them. Some asthmatics have an attack with any little excitement, business worry, or annoyance, but a severe fright is more likely to stop an attack than to cause one.

THE SUPRARENALS IN ASTHMA.

The excitability of different nerve centres shows considerable individual variations. This is shown by the variability of the pupil reflexes, skin reflexes, and deep reflexes. I believe that asthma is due to a condition which is generally, or perhaps always, inborn, and often inherited, in which the bronchomotor part of the vagus nucleus is more active than in the average man. In some cases it is very slightly so; the individual may then never have an attack of asthma in his life or, as in several of my patients, only a few attacks under very special circumstances. In other cases it is very hypersensitive and the asthma is more severe and constant. The overactivity of the broncho-constrictor fibres of the vagus is kept in check by the broncho-dilator activity of the sympathetic nerve-supply to the bronchial muscles, which is largely dependent on the constant secretion of adrenalin.

Physical and mental fatigue is a very common cause of asthma. Many asthmatics are always ill when they over-work, but recover at once on a holiday. Asthma is always worse in the evening than in the morning, and many patients can eat a large breakfast without any unpleasant symptoms resulting; but the smallest dinner, consisting perhaps of no articles of diet which cannot be taken with impunity at breakfast, is followed at once by wheeziness. And even if no food is eaten at night asthma may develop, though less severely. If the patient sleeps in the afternoon he is often less asthmatic in the evening, or if he sleeps just before dinner he may be able to eat much more than would otherwise have been possible. As asthma is caused by over-activity of the bronchial muscles, it might have been expected that fatigue would result in their relaxation, and consequently in the relief of the asthma. But physical fatigue does not seem to influence involuntary muscles, and certainly it does not lead to the relaxation of the bronchial spasm. It is well known that extreme fatigue leads to marked exhaustion changes in the suprarenal gland. It is quite possible that the fatigue of each day is sufficient to cause a slighter degree of similar changes. The smallest diminution in the secretion of adrenalin would allow the over-activity of the vagal bronchomotor centre to have greater play and asthma would result. These considerations appear to afford an adequate explanation of the production of asthma by fatigue.

A toxic idiopathy or hypersensitiveness to a certain protein, according to certain French authors, depends in part upon the fact that the protein has the effect of depressing the activity of the suprarenals. This effect may manifest itself in depression of one or all of its normal activities, the chief being in connexion with the blood-vessels, the alimentary canal, and the bronchi. Acute and severe anaphylaxis produced by large doses of serum injected into an individual sensitised by a previous injection of serum affects all three. More commonly only those functions in which the adrenal control is specially important for the particular individual are affected. Thus an asthmatic will have an attack of asthma and a man with a sensitive vaso-motor system will develop urticaria or other vaso-motor disturbances in the skin. A man who tends to have gastro-intestinal attacks owing to the abnormal irritability of his digestive tract will vomit and have diarrhœa and abdominal cramp owing to exaggerated peristalsis and relaxation of the cardiac, pyloric, and ileo-cæcal sphincters; this explains idiosyncrasies to shell-fish, eggs, and other foods which are manifested by acute digestive disturbances. In some cases an attack of asthma will be accompanied by the vaso-motor changes, or alternate with them, or will be accompanied by the abdominal attack. In one of my patients an attack of diarrhœa is always preceded by a feeling of tightness in the chest, which may develop into definite asthma whilst the diarrhœa lasts, finally disappearing with it. Lastly, in some cases the idiopathy is manifested in an attack of hay fever.

It is a familiar fact that a severe fright may relieve an attack of asthma. A man in the middle of a severe attack was driving downhill when the brake refused to act; he was in immediate danger of dashing into a wall which faced him at the bottom of the hill, but at the very last moment he succeeded in regaining control of the car; when he drew up he found that he was breathing with perfect freedom. This was probably due to the stimulation of the sympathetic and of adrenalin secretion caused by the fright. The stimulation of suprarenal secretion by asphyxia, which is perhaps the cause of second wind in runners, explains also the spontaneous relief or "second wind" which an asthmatic may experience if he continues his exercise after walking has brought on a moderate degree of dyspnœa. Finally, the extraordinarily rapid effect of adrenalin injections in bringing relief to an acute attack of asthma in many individuals can best be explained by this theory. The dose required is less than that required to produce general symptoms, such as a rise of blood pressure and a rapid pulse, because adrenalin first acts upon any organ which is too much under vagal control at the moment. If any intestinal symptoms are present these are likely to be relieved at the same time.

INHERITANCE OF ASTHMA.

All writers have noted the frequency of a family history of the disease in asthmatics, a frequency which is much too great to be accidental. Thus in 39 per cent. of Salter's 217 cases there was a clear history of inheritance. The important question arises: What is it that is inherited? I think that there is sufficient evidence to prove that it is sometimes an irritable bronchial centre, sometimes a toxic idiopathy, and sometimes both. When an individual whose father or mother is asthmatic develops asthma in the absence of any evidence of a toxic idiopathy, or has his first attack of asthma as a sequel of an infection or after he has acquired in adult life a toxic idiopathy, he must have inherited an irritable bronchial centre. For there is no doubt that a toxic idiopathy may be acquired, especially as a result of prolonged exposure to emanations in the course of a man's occupation. In half of Walker's cases which began after the age of 50 the patient was sensitive to a protein with which he came in contact as a result of his work: thus several bakers were sensitive to wheat, an ostler to horse dandruff, and a coffee-sifter to the protein of green coffee husks. Trousseau described the case of a chemist who had a violent attack of asthma when linseed, scammony, and ipecacuanha were powdered in his laboratory, and four others who were sensitive to ipecacuanha only. If no toxic idiopathy is inherited or acquired in an individual who is a potential asthmatic as a result of having inherited a sensitive bronchial centre, he may transmit the tendency to his children without ever developing asthma himself. Thus the paternal grandfather and uncle and maternal grandmother and aunt but neither parent of one of my asthmatic patients suffered from asthma.

An individual may share with some of his relations an abnormal sensitiveness to a certain protein. Coke relates the cases of a woman who was sensitive to milk, and had severe asthma throughout her two pregnancies; both children were fed on cow's milk; the first had gastric symptoms for the first 6 weeks of its life, and the second died from asthma when 6 weeks old. More frequently a general tendency to toxic idiopathies is inherited; Freeman has published numerous instances of this. This may manifest itself in different members of the family as asthma, hay fever, or digestive disturbances, depending upon the inheritance or acquisition of an irritable bronchial, nasal, or digestive system respectively.

TREATMENT.

Three things require consideration in discussing the treatment of asthma: (1) the irritable bronchial centre; (2) the chemical, reflex, and psychical stimuli which may affect the centre; and (3) the attack itself.

1. *The Irritable Bronchial Centre.*

Every asthmatic knows that the better his general health is the less liable he is to asthma. In other words, the irritability of his bronchial centre varies directly with the state of his health. For this reason he should avoid over-work and take adequate holidays. Nothing is likely to do him more good than a month in the Swiss mountains in the winter, where he will probably find that he can indulge in ski-ing, lugeing, and skating with a vigour and freedom from respiratory distress he has not known for months. He should try to take some exercise every day, and a great deal more during the week-end. Slight dyspnœa is no contra-indication, as it often disappears on persevering with the exercise. Most important of all, he should try his best to avoid all possible causes of asthma, as the longer he remains free from it the less irritable the centre will become, until finally after some years of inactivity it may cease to respond at all to stimuli which in the past invariably gave rise to attacks. The best cure of asthma is not to have it. It is almost always possible to find some place where the patient does not get asthma, and no asthmatic child should be allowed to go to a school where he is more or less constantly asthmatic.

I have found that the irritability of the bronchial centre can be to some extent reduced by giving between 3 and 5 grains of caffeine, with double the dose of phenazone, when the patient feels slightly asthmatic and fears that an attack will develop later, as, for instance, immediately after lunch and dinner or on going to bed.

2. *Chemical, Reflex, and Psychical Stimuli.*

(*a*) *Toxic idiopathies.*—When asthmatic attacks are caused by food proteins all that is generally necessary is to exclude from the diet the food to which the patient is found to be most sensitive by the cutaneous test. Long abstention probably results in desensitisation. If eczema or urticaria is present it often disappears at the same time. Desensitisation does not follow injection of the proteins or feeding in slowly increased quantities of the food. Desensitisation to pollen can almost invariably be brought about by the subcutaneous injections of progressively larger doses of the pollen extract during the weeks preceding each hay-fever and hay-asthma season.

A patient can often free himself from asthma by imply avoiding any animal to which he has been hown to be sensitive, or in the case of feathers by oiding feather pillows, mattresses, and upholstery. hen an asthmatic is sensitive to horse dandruff in ilution of 1 in 10,000 or more desensitisation is necessary, as the dust of city streets contains sufficient of the protein to cause attacks. In such cases, and whenever avoidance of the animals is impossible or does not relieve the asthma, desensitisation should be undertaken with the specific proteins. Nothing but specific treatment is of any use; thus an individual who is sensitive to horse serum can be desensitised with the serum if it is necessary to give him some antitoxin, but this has no effect on his asthma, even if he happens to be also sensitive to horse-dandruff proteins. A large proportion of cases are relieved; at the same time the skin reaction disappears or is greatly reduced in intensity.

Idiopathy to bacterial toxins can generally be overcome by vaccination in the ordinary way with organisms isolated from the patient's bronchial secretion or material obtained from other infective foci. In determining which organisms are most important the cutaneous reactions give some help, but even if no reaction is obtained an autogenous vaccine may prove very useful in curing chronic bronchitis or rhinitis which has acted as a reflex cause of asthma. The reaction is generally negligible if the injection is made at night and the patient takes 10 or 15 grains of aspirin at the same time. Lastly, the daily life of each patient should be investigated in every detail in an attempt to find some special toxic idiopathy other than the familiar ones already described, which may be in part responsible for the asthma.

(*b*) *Reflex causes.*—Bronchitis should be treated by autogenous vaccines and small doses of iodide taken for long periods. A careful examination of the nose should be made and any obvious source of irritation should be removed, but no operation should be performed unless it is very clearly indicated, as I have seen several cases aggravated by such operations, and one of the worst cases I ever saw was a man of 50 who had his first attack of asthma immediately after a hypertrophied turbinal had been removed. I have seen several cases in which mere cauterisation of a sensitive point on the septum in an apparently normal nose, as advocated by Francis, has produced marked improvement, though rarely, if ever, complete disappearance of all attacks. In many cases an autogenous vaccine prepared from the nasal secretion will do away with the need for local treatment by relieving the congestion which is secondary to infection, and in any case it is a useful preliminary measure in order to diminish the severe reaction which occasionally follows an operation. Apart from the Friedländer bacillus, already referred to, Dr. Eyre finds that the *B. septus* isolated from the nasal secretion, and pneumococci, *M. catarrhalis* and streptococci from the nasal and bronchial secretion are the organisms most frequently found in the rhinitis and bronchitis associated with asthma.

Asthma caused by a gastro-bronchial reflex can be avoided by eating hardly anything for dinner, which should be as early as possible, and nothing at all on going to bed, as the reflex only comes into play as the day advances and the patient becomes more tired. I have already pointed out how much benefit he may derive by sleeping or resting for half an hour before his evening meal. Regulation of the quantity of food is of more importance than its quality, except for any toxic idiopathies which may be present, but the food, especially in the evening, should be as digestible as possible; no better guide to a suitable diet could be found than that given in Dr. James Adam's little book on "Asthma."

The intestinal-bronchial reflex comes almost entirely from the pelvic colon and rectum, and regular habits and exercises to overcome dyschezia are generally sufficient to keep it in check. Aperients should be avoided as far as possible, but in some cases a small weekly dose of infusion of senna is needed to prevent a fæcal accumulation from forming.

(*c*) *Psychical causes.*—Psychotherapy is only useful in so far as explanation of the mechanism involved may lead an asthmatic to take a less hopeless view as to his chance of complete recovery. So long as he feels convinced that certain circumstances will inevitably cause an attack they will certainly do so. He should be persuaded to be optimistic about his condition, and hope and even expect that what has hitherto caused an attack will not necessarily do so in the future.

3. *The Attack.*

An attack of asthma can most readily be cut short by the subcutaneous injection of adrenalin. The most efficacious dose is very much smaller than that generally given. In many cases a single minim of 1 in 1000 adrenalin chloride is enough, more than two minims being rarely required. But the injection should be given at the beginning of an attack, directly a patient wakes in the night, for instance, and not half an hour or an hour later when it has reached its full development. The relief is so immediate that the patient often falls asleep within five minutes of waking in an attack. Such small doses give rise to no unpleasant sensations, such as frequently follow the injection of three or more minims, and the blood pressure does not rise at all. Consequently the treatment can be continued for long periods without any fear of ultimately causing arterio-sclerosis. It is the only form of injection which a patient should be allowed to use on himself; if he has to depend on someone else giving the injection he will rarely receive it at the right moment.

For slight attacks and for the feeling of slight dyspnœa, which may persist throughout the day when severe attacks occur at night, atropine and cocaine may be used with an atomiser.

No patient should be allowed to use any of the numerous powders which are used by inhaling the fumes produced when they are burnt, as they invariably aggravate any bronchitis which may be present, and actually give rise to bronchitis in patients who have hitherto been free from it. I have seen several patients who have only recovered from a prolonged attack of asthma, persisting for weeks or months, after they had been persuaded to spend their nights sleeping in an easy chair instead of lying down in bed. Lastly, I wish to emphasise the fact that these remarks on the treatment of the attack should not make us forget that our chief aim must be to devise such a course of action for the patient that he will eventually have no attacks to treat.

ST. BARTHOLOMEW'S HOSPITAL: TREASURER'S REPORT.—This report, dealing with the year 1920, opens with a statement regarding the policy of asking payment from both in-patients and out-patients, that policy being in accord with the principles laid down by King Edward's Hospital Fund for London. A review of the causes of the increased expenditure of the hospital and the means which have been adopted to meet it afford instructive information on hospital management generally, and is worthy of attentive perusal. During the year under notice 8401 in-patients were admitted, making, with the 507 patients who were under treatment on Jan. 1st, 1920, a total of 8071. The casualty patients (first attendance) were: medical, 30,385; surgical, 38,219. Street accident and illness cases brought to the hospital by ambulances or hand litters belonging to the Corporation of the City of London or to the County Council numbered 2203 The statistics dealing with the treatment of discharged sailors and soldiers show that 331 pensioners were admitted into the wards, the total attendance for out-patient treatment being 26,018.

A Lecture
ON
MITRAL STENOSIS.

Delivered at the National Hospital for Diseases of the Heart,

BY BASIL PARSONS-SMITH, M.D., M.R.C.P. LOND.,
PHYSICIAN TO OUT-PATIENTS, THE NATIONAL HOSPITAL FOR DISEASES OF THE HEART; HEART SPECIALIST, MINISTRY OF PENSIONS.

OF the several varieties of heart disease which are valvular in origin mitral stenosis will, at all times, occupy an important and prominent position; it is an example of the progressive maladies which sooner or later in their course evince signs and symptoms of myocardial incompetence in association with some existing valvular defect; moreover, mitral stenosis occupies a position of relatively high importance, being a condition of extreme prevalence, and also for the reason that definite clinical indications invariably exist which inform us of the progress of the disease and provide all the evidence needed for accuracy in prognosis and success in treatment.

Mitral stenosis may be broadly defined as a type of those diseases which are somewhat slow to proclaim their presence with certainty; this is easily understood, for the narrowing of the valve can only be produced by gradual stages, and the cicatrising process, however originated, must inevitably proceed slowly. As regards sex-incidence, all authorities are agreed in finding this disease more common in the female than the male, probably owing to the fact that rheumatism and chorea, the two conditions which undoubtedly originate endocarditis in the majority of cases, are more prevalent in the female. The disease is essentially one of early adult life, statistics all going to prove the extreme frequency of the condition between the ages of 20 and 35 years.

ÆTIOLOGY.

The ætiological factors may be discussed under two headings: (1) acute infections; (2) degenerative processes. A third group may perhaps be mentioned to include rare types of the disease due to strain, trauma, congenital malformation, &c.; these need not detain us. Of the acute infections which initiate early changes in the tissues of the valve and its adjoining structures, the rheumatic group of diseases predominates in overwhelming fashion; but measles, scarlet fever, small-pox, erysipelas, pneumonia, septicæmia, &c., account for a considerable number of cases.

Group (2) comprises the types of the disease which are *secondary to degenerative processes*; retrograde changes which take place with advancing years, whether they be secondary to some form of toxæmia, long-continued strain, or other causes, may be responsible for valvular disturbance and disease; hence the association between degenerative processes characterising such diseases as gout, syphilis, chronic nephritis, plumbism, arterio-sclerosis, &c., and valvular lesions, in which fibrotic changes, adhesions, retractions, and other such-like malformations are gradually produced; it should, however, be remarked in passing that all the evidence at our disposal points to the factors mentioned in Group (1)—viz., acute infections, materially outweighing degenerative lesions in relative importance, so that, for practical purposes, we may regard mitral stenosis as a disease caused by the chronic inflammatory process following endocarditis which leads, sooner or later, to thickening and fusion of the valvular cusps.

The first manifest result of the stenosis will clearly be centred round the obstruction, which interferes with the even blood flow from the left auricle above to the ventricle below, and the influence it exerts upon the cardiac mechanism and output; in the early stages of the disease it is evident that the heart's main difficulty will be adequately to maintain the filling of the left ventricle, to which the inflow will be slowed by the lesion; a disturbance will therefore arise in the relative pressures, venous and arterial—pressure in the left auricle and pulmonary veins being raised at the same time as the amplitude and force of pulse diminishes in the aorta and its branches; this dislocation of the normally balanced pressures evokes rapid response on the part of the cardiac musculature, which utilises its reserve of energy by increasing the working capacity of the left auricle and right ventricle, so tending to counteract the effects of the lesion, and to maintain an efficient relation between the pressures of the systemic and lesser circulations respectively. In varying degree and for varying periods of time we find, therefore, that the reserve power of the cardiac muscle is sufficient to deal with all the altered circumstances resulting from mitral stenosis, and only when there is definite evidence of the diminution of this reserve of energy will cardiac failure be produced in recognisable form.

DIAGNOSIS.

Symptoms.—Apart from exceptional cases which by reason of their freedom from symptoms may be regarded as latent, the majority of patients with definitely diagnosable mitral stenosis are subject to sensations of discomfort causing varying degrees of physical incapacity. By reason of the interference with pulmonary circulation, and resultant deficient aeration, the patient will usually complain of breathlessness—at first produced only by strenuous effort, extreme emotion, &c., but increasing in intensity, developing under milder provocation, and, in the latter stages of the disease, disturbing the patient at rest, becoming persistent, and tending to produce acute exacerbations from time to time, for no very apparent cause; this last is true paroxysmal dyspnœa, or so-called cardiac asthma.

Linked closely with the sensation of breathlessness, and depending upon similar causes, is the cough which develops with uniform regularity and tends to persist. The sputum as a rule is very fluid, frothy, and frequently tinged with blood; in this disease, more often than in any other valvular affection, pulmonary hæmorrhage is likely to take place with free hæmoptysis; persistent attacks of bronchitis frequently result from apparently trivial causes. Præcordial pain and tenderness are often complained of, and may prove a definite and obstinate incapacity, especially in certain aggravated cases where the pain may assume all the attributes of true angina; otherwise it is customary to find varying degrees of epigastric pain and distress due to hepatic engorgement, also some amount of discomfort under the left breast secondary to disturbances of the gastro-intestinal tract. Attacks of tachycardia and palpitation, also headache and giddiness, are often annoying symptoms. As the disease progresses and cardiac failure becomes more evident the symptoms develop in intensity, and further debilities arise as a result of stasis, which depends upon the inefficiency of the myocardium to maintain the necessary balance of the circulatory mechanism.

A broad review of the symptoms of mitral stenosis shows that they differ but little from those associated with cardiac failure secondary to other varieties of valvular lesions; it is, however, important to appreciate the early appearance of pulmonary complications in this disease, the not infrequent crises which indicate arterial embolism, and the brassy cough, aphonia and hoarseness which certain cases develop as a result of damage to the left recurrent laryngeal nerve.

Physical Signs.

Turning to the question of physical signs, these ond a complicated series of phenomena which can sibly be discussed to the best advantage if we divide the disease into stages; for this purpose it is necessary to analyse the clinical picture with some care. Stage 1 deals with the disease in its undeveloped form, Stage 2 refers to the period of full development, and Stage 3 with that advanced state of the malady in which the failing heart suffers the additional strain and handicap imposed by the change of rhythm, the gross irregularity associated with fibrillation of the auricles.

Stage 1.

The value of a correct appreciation of this undeveloped stage cannot be too strongly emphasised; as the result mainly of post-mortem examinations, and for other no less definite reasons the narrowing of the valve aperture is known to be produced only by slow degrees and in the gradual manner typical of the formation of scar tissue, so that there must be a clearly defined interval between the primary invasion of the valve curtains and the ultimate development of the stenotic process. This interval of time will of necessity be elastic, depending upon the virulence of the first infection, the patient's resisting power, domestic circumstances, sex, occupation, the possibility of a secondary infection, &c.; for clinical purposes, and as a general working rule, a period of from three to six years may be taken as essential for these early changes. During this interval the early symptoms of cardiac failure, including shortness of breath with moderate effort, undue exhaustion, palpitation, general cardiac overaction, &c.—in short, the whole symptom-complex of an impaired exercise tolerance—will tend to become increasingly noticeable; physical signs are few, but by careful examination sufficient can be detected for diagnostic purposes.

The outstanding features helpful in an endeavour to spot the disease prior to its full development may be of two varieties, negative or positive; the negative indications include the following: (1) A normal general appearance with a healthy facial aspect; (2) a heart of normal size, whose resting rhythm is quiet and regular; (3) a pulse regular in time, and normal in size and pressure; (4) entire absence of venous engorgement, jugular, pulmonary and visceral.

The positive indications refer mainly to the sounds of the heart and their variations under different conditions, more especially in those patients, the recent victims of some acute infection, whose reserve of energy is beginning to manifest a restricted field of response. On auscultation, alteration in the quality and pitch of the two heart sounds is at once realised; the first sound is loud and prolonged, approaching the variety described as snapping, and a systolic murmur may or may not follow it; the second sound may be reduplicated at the apex or base, or the normal third heart sound may be audible at the former situation; under special conditions a presystolic murmur will be audible at the apex region; its evanescent appearance is noticed with the tachycardia or raised rate of beat following effort, when the maximum effect of the early valvular damage is in full operation. This fact then provides a diagnostic key of great value in clinical medicine, enabling us to recognise the presence of valvular cicatrisation in its very early form, and to understand that the developing lesion passes through a definite stage during which its ill-effect upon the heart's mechanism is manifested only when an extra demand is made upon the circulation and the heart rate, in consequence, is unduly raised.

The practical deduction we arrive at is that, before excluding mitral stenosis, we must, in doubtful cases, examine the heart's sounds both in the active and resting phases; the active stage may be rapidly produced by instructing the patient to carry out some form of muscular effort; this being completed, auscultation is at once proceeded with, preferably in the recumbent position; more often than not, probably, the typical murmur preceding and running up to the loud first sound is audible only for quite a few beats after the exercise when the lesion is an early one; later the murmur will persist for a long time after its production, and its presence will be noted following efforts very slight in character—even after simple changes of position, from back to left side when lying, &c. In certain cases physical exercise may for some reason be contraindicated, and some alternative method of acceleration of the heart must be adopted—as, for instance, inhalation of amyl nitrite or subcutaneous injection of atropine—to remove temporarily the controlling influence exerted under normal circumstances by the autonomic nervous system through the vagus nerves.

By one of these ordinary methods it is invariably possible sufficiently to raise the heart rate for diagnostic purposes; the presence of the early stage of mitral stenosis may be confidently assumed in cases which manifest the typical presystolic murmur, however fleeting the latter may be.

Stage 2.

Passing next to the period of full development of the lesion a clinical picture is recognised displaying the following complex series of physical signs. Certain striking peculiarities in the facial appearance are seen—a dusky malar flush, with a tendency to cyanosis of the lips and mucous membranes generally, is commonly but not always observed; frequently the facial aspect is one of profound anæmia in spite of the invariable abnormally deepened tint of the lips. Peripheral cyanosis is usual, and clubbing of the fingers may be present.

The præcordium is frequently unduly prominent, and a variety of abnormal signs are observable by inspection of this area; the apex beat is wavy and diffuse, involving several spaces, and extending unusually far to the left of the mid-sternum; systolic retraction of the area to the left of the sternum, which overlies the right ventricle, can be detected in many cases where cardiac overaction is present, and a systolic impulse may sometimes be seen in the second left interspace, depending upon the exaggerated pulsation of the pulmonary artery.

Palpation reveals phenomena of outstanding importance; at the apex a fine purring thrill, which terminates in a short tapping systolic shock, at once attracts notice; the duration of the thrill may occupy the whole or only a portion of the diastolic interval; in the majority of cases it is sharply localised to the immediate vicinity of the apex beat, otherwise a wider diffusion will obtain, especially in patients whose chest walls are thin and wasted. In addition to the palpable shock of the first sound at the apex region there may be present also a well marked shock, diastolic in time, at the pulmonary area, produced by the forcible closure of the pulmonary valves.

The pulse at the wrist is usually small, and, until the development of the final stage of the disease, fairly regular; premature breaks are a frequent occurrence; the systolic blood pressure differs but little from the normal; as a result of generalised vaso-constriction there is often an undue elevation of the diastolic reading, accounting for the diminished pulse volume observed with such uniformity in mitral stenosis.

In the region of the apex cardiac dullness may not exceed the normal limit, but with the progress of the malady some cardiac hypertrophy will develop, so that the left border of the dullness will extend unduly in the direction of the axilla, and the right margin will reach to, or even beyond, the right sternal edge, depending more especially upon the size and degree of engorgement of the right auricular chamber. At the base of the heart the limit of dullness extends higher and farther to the left than is ordinarily the case, indicating enlargement of the conus arteriosus and pulmonary artery.

The auscultatory signs by which mitral stenosis is recognised are admittedly complex, differing remarkably in essential detail from the phenomena which determine the diagnosis of the other varieties of valvular mischief, and also changing materially with the progress of the disease. Mindful of the presystolic murmur, which can be rendered audible by appropriate methods in the early stages of the disease, one can perhaps more readily appreciate the significant changes revealed by auscultation when the narrowing process becomes fully developed; they may be taken to include:—

1. An apical presystolic murmur whose pitch and intensity rise with extreme rapidity to terminate in a loud snapping first sound.

2. An apical diastolic rumble, which, commencing shortly after the second sound, may extend up to, and mingle with, the presystolic murmur. It therefore happens quite frequently that a long murmur occupies the whole period of diastole, commencing with the opening of the auriculo-ventricular valves and terminating at their closure; the first part of the murmur depends upon vibrations set up by the flow of blood through the constricted mitral orifice, the latter or crescendo portion being produced by the auricular contraction, which of necessity becomes an extremely forcible event in this disease.

3. A systolic murmur at the apex, indicative of mitral regurgitation, rendered inevitable by the sclerotic changes which induce varying degrees of rigidity of the valve and incidentally obviate its closure.

4. An accentuation of the second sound at the pulmonary area indicative of a rise of pressure in the lesser circulation.

5. A diminution, possibly an entire absence, of the second sound at the apex, which we may infer is the result of the lessened output of the left ventricle, and the reduction in systolic blood pressure.

6. A diastolic murmur audible at the left sternal margin, described by numerous observers, and attributed to a functional insufficiency of the pulmonary valve, but having little beyond an academic value, and calling for comment on account of its resemblance to the diastolic murmur of aortic insufficiency; several important differences will, however, guide a differential diagnosis between the two lesions; the close proximity of the aortic and pulmonary orifices, and the fact that incompetence of either occasions a similar type of murmur with maximum intensity in the region of the third left interspace at the costal margin, make it plain that the propagation of the murmurs is likely to differ; for practical purposes the pulmonary diastolic murmur is sharply localised, whilst the murmur of aortic incompetence is conducted by the blood stream not only to the region of the apex but also to the aortic area and systemic vessels; moreover, the latter murmur is accompanied by an easily recognised collapsing quality of the pulse.

Stage 3.

The third and final stage of mitral stenosis has reference to that period of the disease in which all the extreme symptoms of heart failure develop, secondary not only to the advanced degree of the valvular narrowing, and to the coexisting myocardial changes, but also to the onset of auricular fibrillation, which produces a rhythm of such gross irregularity as seriously to embarrass the heart's functional capacity; so frequently, moreover, does auricular fibrillation arise in the latter phases of mitral stenosis, that its development may be regarded as a certain indication that the malady has reached its terminal stage.

As a rule patients are fully conscious of the degree of their disease at the time of the appearance of auricular fibrillation; existing symptoms are aggravated, reserve power is further curtailed, physical signs of extreme failure tend to become increasingly evident, and complications of a serious character are likely to develop; hence it is highly important to possess an adequate supply of evidence for the recognition of auricular fibrillation.

Points Revealed by Examination.

An ordinarily careful physical examination will generally give all details necessary for diagnostic purposes, but instrumental investigation, either by means of the electrocardiograph or the clinical polygraph, may also be required.

The main points revealed by examination are the following:—

1. The gross irregularity, and usually the extreme frequency of the heart beat, the former being more evident with the higher rates.

2. The discrepancy which often obtains between the rates of heart and pulse, several of the smaller contractions of the former being apparently unable to produce an appreciable arterial pulsation.

3. An alteration in the auscultatory phenomena at the apex region; the presystolic murmur is no longer audible, the auricle being unable to execute coördinate contractions; the accentuated first sound will, however, persist, also the systolic murmur; the diastolic murmur, if previously present, will remain.

These important physical signs merit most careful consideration, as they provide ample evidence for the diagnosis of auricular fibrillation, and prove that, in the majority of cases, instrumental methods are merely confirmatory agents; the polygraph curve displays to great advantage the irregularity of the force of the heart beat and the entire absence of anything approaching a dominant rhythm, and also a venous curve of the ventricular form; the electrocardiograph will show ventricular complexes pursuing a rhythm of perpetual irregularity and varying in height from beat to beat; an entire absence of "P" waves preceding the ventricular complexes is also observed together with the presence of certain minute waves between the ventricular beats indicative of the small movements of the auricular musculature. Auricular fibrillation may thus be readily detected by ordinary examination in most cases; experience shows that this disorder will generally be permanent and largely responsible for complications, being also the underlying factor on which depends the aggravation of symptoms and signs. The latter progress with varying rapidity, differing little in detail from those which characterise the cardiac failure accompanying other forms of chronic heart disease; the heart enlarges considerably, and evidence of stasis in the pulmonary circulation becomes increasingly evident; with gradual intensification of myocardial weakness venous engorgement tends to become a conspicuous feature; serous effusions develop, and before long the following complications will appear:—

1. *Alterations in rhythm.*—Of these the most important is that which characterises auricular fibrillation considered above; mention may also be made of premature contractions, which frequently disturb the existing rhythm of the heart beat, and of intermittently occurring attacks of tachycardia—of simple type, due to temporary acceleration of the normal rate of beat, or true paroxysmal tachycardia, in which the seat of origin of the heart's contraction has shifted temporarily from the normal situation—and the irregularity of rhythm which depends upon the intermissions of heart-block, a not infrequent process in the spread of myocardial degeneration.

2. *Pulmonary.*—These include bronchitis, pulmonary congestion, and hæmoptysis; the lesser circulation being engorged, small vessels frequently rupture, and the sputum in consequence becomes blood-tinged; at times profuse and obstinate bleeding may seriously prejudice the patient's condition.

3. *Paralysis of the left recurrent laryngeal nerve.*—In a small percentage of cases this nerve becomes paralysed; in consequence the voice becomes weak and the cough brassy; the nerve injury is produced by slow and gradual compression, depending directly upon the upward pressure exerted by the enlarged left auricle on the left pulmonary artery.

4. *Cerebral embolism.*—This may occur as the result of the detachment of a small vegetation from the valve surface, or by the escape of a small fragment of clot from the cavity of the dilated auricle, where thrombus formation is a usual event after the onset of fibrillation.

5. *Attacks of angina pectoris.*—Pain and præcordial distress are quite usual in cases of mitral stenosis, but true angina pectoris is apparently comparatively rare in this disease.

Morbid Anatomy.

The mitral orifice is narrowed and distorted; the opening may be reduced to a mere slit between the rigid margins of the valve, or may take the form of a small circular orifice at the bottom of a dense sclerotic funnel extending downwards for a varying ngth from the region of the mitral ring; the margins of the valve are thick, irregular, and possibly studded h vegetations; the surface of the valve cusps is uneven, presenting a scarred and puckered appearance; dense masses of fibrous tissue extend from the bases of the valves, involve the angles where the cusps adjoin, and weld the valve structures firmly together; the chordæ tendineæ are shortened and thickened into dense white cords; the left auricle is enlarged; its wall is hypertrophied, both endocardium and musculature being involved in the process; the dilated cavity of the auricle frequently contains one or more globular thrombi; the pulmonary veins at their entrance to the auricle are considerably dilated; the condition of the left ventricle varies—in the majority of cases it i definitely hypertrophied, but sometimes there is a apparent reduction in the thickness of the chamber walls, resulting from a diminished entry of blood; the right ventricle is invariably hypertrophied; the lungs are enlarged, and their tissue is abnormally firm by reason of chronic venous stasis and of coexisting fibrotic changes.

Treatment.

With a full appreciation of the varied clinical picture presented by the disease during its progress, and of our limitations in the matter of interference with fibrotic changes and sclerosis in the structure of the valve, we know that certain forms of treatment may delay the course of the malady, and add effectually to the comfort of the patient. In the early stages all possible preventive measures should be adopted; the patient should be instructed to lead a quiet, regularly-ordered life, free from worry, anxiety, or physical strain; exercise in the open air, short of the least suspicion of fatigue or distress, is important; strenuous games and pursuits must be forbidden, but amusements such as golf, cycling on the flat, walking, light gardening, or other similar hobby may be allowed. An ordinary easily digestible diet in moderate quantities should be taken; the value of adequate mastication and the necessity of a short rest after each meal should be emphasised; smoking should be forbidden, to obviate irritation of lung tissue which is already the seat of some degree of venous engorgement. Shortness of breath, a slight cough, and others of the early symptoms are frequently associated with poor nutrition or some degree of anæmia, and will respond to dietary changes, a course of iron and arsenic or other simple measures.

Deficient exercise tolerance, undue exhaustion with moderate effort, palpitation, præcordial discomfort, &c., are common indications that the reserve power of the heart is suffering reduction; weakness of the heart muscle becomes unmistakable; small doses of digitalis should be prescribed in short courses. The most efficient method to adopt is to give a moderate dose (e.g., ℳ x. of tincture of digitalis) three times daily on two days (Saturday and Wednesday) in the week, or, as an alternative, to prescribe a larger dose (e.g., ℳ xx.-xxx. of tincture) every third day at bedtime; this line of treatment will usually be attended with much relief to the patient; bronchitis, cough, and pulmonary congestion, common complications in mitral stenosis, are more likely to be relieved by treatment of the heart than by expectorants or other agencies directed towards the lungs; if the sputum is tenacious and the cough irritable it is, however, wise to prescribe a simple expectorant mixture combined with some reliable sedative, such as tinct. camph. co.

Hæmoptysis in small amounts does not call for special treatment; if excessive the patient should be kept at rest, and morphia in small doses may be given; premature contractions and attacks of paroxysmal tachycardia are frequent events failing, as a rule, to respond to treatment; fortunately the patient is not invariably conscious of their presence, and in such cases it is advisable to disregard their occurrence. With the arrival of auricular fibrillation there is usually intense aggravation of all existing signs; the first indication is complete rest from bodily exertion and from anxiety or worry of any kind; digitalis should be prescribed in large doses until its full physiological effect is produced; it will be well, unless cardiac failure is extreme, to commence with a dose of 20 minims of the tincture every four hours: this is usually found to be sufficient to produce a satisfactory reaction in three to four days; having reduced the rate of heart beat to reasonable limits, it is advisable to diminish the dose of the digitalis, endeavouring, during the process, to maintain the rate between 70 and 80.

In certain cases the well-known toxic effects of digitalis may be produced; prescription of this drug must always be undertaken with extreme caution; the tendency to gastric disturbance may at times be obviated by giving the digitalis in ice-cold albumin water, or mixed with a small quantity of brandy; in other instances the drug may be given in pill form, the digitalin granules of Nativelle being perhaps the most satisfactory. The beneficial effect of digitalis upon the heart may so improve the whole physical state of the patient that other complications requiring special treatment may not arise; in the later stages of the disease, however, certain important debilities usually become manifest, and we must be prepared to adopt quite early all the principles of a well-judged and cautious therapy.

Diet is important; light, easily-digestible articles of food should be selected; the meals should be small in bulk and taken at frequent intervals; the amount of fluid should be considerably curtailed, especially if any tendency to dropsy be observed; gastric catarrh, if obstinate, will best be treated by stopping all food for two or three days, only ice, with possibly a small amount of stimulant, being allowed during this time; diet may be cautiously resumed later, beginning with milk and lime water, effervescing drinks, beef juice, bread and milk, egg albumin, &c., in combination with medicinal agents, such as hydrocyanic acid, oxalate of cerium, tincture of iodine, or carbolic acid. In moderation the patient may be allowed to gratify his own fancies; in the first few days jellies, custard, biscuits, toast and some variety of appetising sandwich, will be appropriate, leading later to eggs in some form, boiled fish, scraped beef, fowl, sweetbreads, &c., with a small amount of some favourite vegetable; fresh fruit in the form of grapes or oranges may be encouraged; fluid should include milk and soda, weak tea or coffee, lemonade, and barley water; a small glass of champagne with the lunch and supper may be prescribed with advantage.

Without sufficient sleep recovery will tend to be very protracted; it may be sufficient if the patient takes some warm stimulant, such as whisky or cognac, or some mild hypnotic—a small dose of ammonium bromide, sulphonal, trional or veronal—may serve to induce sleep; obstinate insomnia necessitates prescription of chloral or opium in some form; for extreme dyspnœa morphia is invaluable, and should be given without hesitation.

Palpitation is a most distressing symptom, improvement of which should come about with the diminished heart rate produced by the digitalis medication; otherwise it will be well to try the effect of an icebag to the præcordium, or counter-irritation by some one of the well-known methods; palpitation is frequently secondary to flatulent indigestion, and efficient treatment of the latter will result in its complete disappearance. For dropsy, which so often aggravates the physical condition, a mercurial purge may be all that is necessary, or some simple diuretic mixture, or the compound digitalis pill which contains both mercury and squills in addition to the digitalis powder; more obstinate cases necessitate the use of Southey's tubes or acupuncture; massage and careful bandaging frequently control the mischief and always add to the comfort of the patient. Serous fluid collecting in any of the visceral sacs should be carefully watched and removed if it interferes with the functions of the organs involved.

Extreme degrees of failure may develop at any time in patients in the final stages of mitral stenosis; in such cases *strophanthin*, administered by intravenous injection, may prove beneficial; diffusible stimulants as ammonia and ether, and other rapidly acting drugs, such as caffeine, strychnine, and camphor, may produce temporary reactions which serve to tide the patient over the critical period; in the presence of venous engorgement, with much distress in breathing, a venesection will give immediate relief; as an alternative method leeches may be applied over the hepatic area or right auricle; in either case oxygen should be simultaneously administered by inhalation.

THE DIAGNOSIS OF DYSENTERY BY THE SIGMOIDOSCOPE.*

BY PHILIP MANSON-BAHR, D.S.O., M.D.CANTAB., M.R.C.P.LOND.,
PHYSICIAN TO THE HOSPITAL FOR TROPICAL DISEASES AND ALBERT DOCK HOSPITAL, LONDON; LECTURER, LONDON SCHOOL OF TROPICAL MEDICINE;

AND

A. L. GREGG, M.A., M.D., B.CH., B.A.O.DUB.,
MEDICAL SUPERINTENDENT, HOSPITAL FOR TROPICAL DISEASES, LONDON.

A SEARCH through numerous papers on dysentery which have appeared during recent years has revealed the fact that the advantages to be gained by the routine use of the sigmoidoscope in the diagnosis of, and as a guide to treatment in, chronic dysentery have hardly been appreciated, at any rate in this country. In a monograph which has recently appeared, illustrated by a series of beautiful plates,[1] Bensaude has described the main features of amœbic ulceration as seen through the sigmoidoscope, its differentiation from chronic bacillary lesions and from other diseases of the rectum which may give rise to diarrhœa or dysenteric symptoms. He maintains that the amœbic lesions as observed through this instrument differ considerably from those usually seen at autopsy in being more superficial and much paler in colour. There is a short reference to this subject by Lyons[2] in a general paper on the status of amœbic dysentery in the United States; he has noted that, apart from giving the observer a good view of the ulceration, the diagnosis may be confirmed by the presence of the *Entamœba histolytica* in scrapings obtained from the ulcers, even where the stools have been searched in vain for these organisms. This observer has further recorded his opinion that no case should be discharged as cured without a proctoscopic examination. If this rule were universally adopted, he thinks, there would be fewer relapses and fewer drugs described as specifics.

It is hardly necessary to emphasise that this subject is of very considerable importance at the present time when a very large number of war pensioners are receiving treatment in special hospitals for chronic diarrhœa or dysentery.

In the acute stages of dysentery of both the amœbic and bacillary varieties the routine use of the sigmoidoscope is hardly indicated; usually, in practised hands, a correct diagnosis can be made by laboratory methods. It is in the peculiarly chronic and intractable cases resulting from an original infection acquired three or more years ago, where the laboratory, for reasons shortly to be detailed, can afford little assistance, that familiarity with sigmoidoscopic diagnosis proves very desirable.

During the last year we have used this instrument as a routine measure in making our diagnosis of

---

* An abstract of this paper was read before the Society of Tropical Medicine and Hygiene, Jan. 21st, 1921.

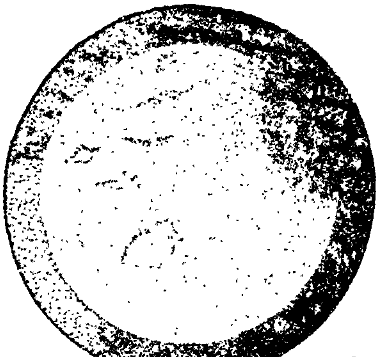

FIG. 1.—Amœbic dysentery.—Typical ulceration with hæmorrhagic margins and isolated hæmorrhages (8 ins. from anus).

Sigmoidoscopic Appearances in Dysentery.

Figs. 1-3 and 5-7, reproduced from the author's water-colour drawings, have lost some of the finer distinctions in the process. Fig. 2 is rendered the same size as the original drawing in order to give an idea of the actual image seen by means of the instrument. The others are about half scale.

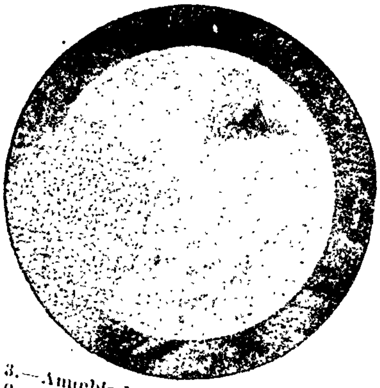

FIG. 3.—Amœbic dysentery.—Showing two superficial ulcers, dark blood clots of some considerable size. Numerous entamœbæ demonstrated in scrapings of ulcers; none found by microscopical examination (2 ins. from anus).

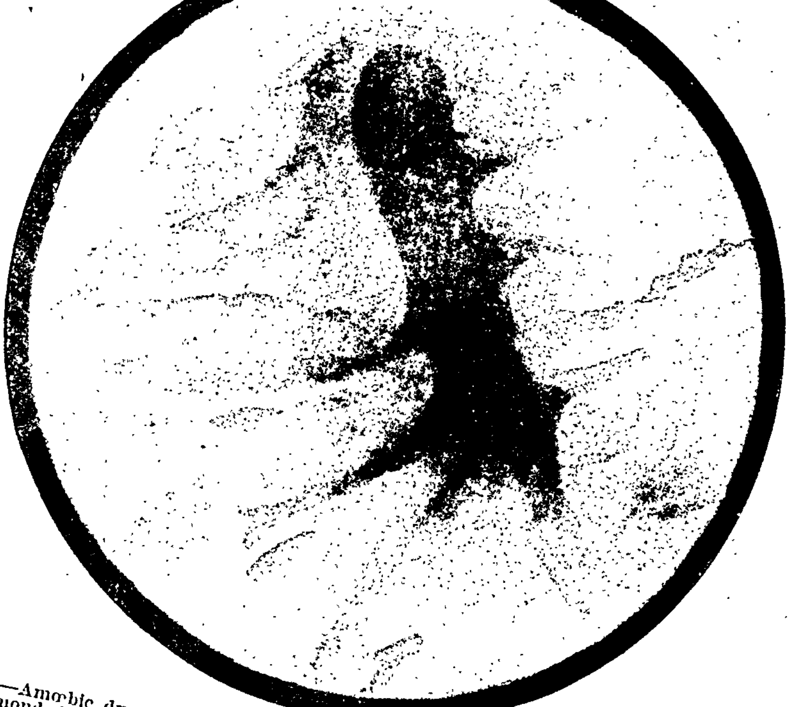

FIG. 2.—Amœbic dysentery.—Showing redundant mucous membrane, superficial diamond-shaped ulceration, and dark hæmorrhagic clots (4 ins. from anus).

dysenteric cases among war pensioners at the Hospital for Tropical Diseases, and we can confirm the statements already quoted as to its great utility. In fact, as the result of this work, we venture to qualify considerably the views already expressed.

It is hardly necessary to state that quite a number of our amœbic cases gave no history of "dysentery," as this term is generally understood—that is to say, the appearance of blood and mucus in the stools—but rather complained of attacks of recurrent diarrhœa; in fact, it would be much more appropriate to describe these cases of amœbiasis as "amœbic diarrhœa," a term which Dobell[3] has already sanctioned. The clinical history which one can obtain in these cases, the oft-repeated story of relapses of "diarrhœa" and "dysentery" alternating with periods of quiescence and the fact that the majority of these men originally contracted their dysentery in countries where *Entamœba histolytica* is widely distributed, would primarily suggest that the majority are amœbic in origin, but it is a fallacy to presume that all are due to this organism. A certain number are due to other causes, and in them the intestinal symptoms are by no means improved, it may be they are actually aggravated, by a misdirected anti-amœbic treatment. On the other hand, we have found that it is not wise always to assume that the patient's present symptoms are ue to a recurrent bacillary infection, even in cases whom the specific dysentery bacillus was primarily lated during the war, for occasionally we meet th cases who, though undoubtedly in the first instance the victims of bacillary dysentery, have subsequently contracted amœbiasis.

Unfortunately mere physical examination of these chronic dysentery cases affords but little assistance in making a definite diagnosis. As a general rule, chronic bacillary cases are more emaciated and debilitated than are the victims of chronic amœbiasis; this is probably due to the more extensive destruction of the intestinal mucosa which occurs in the former disease, and to a chronic toxæmia from secondary organisms. In amœbiasis, by abdominal palpation, areas of deep tenderness can generally be elicited over isolated portions of the large intestine such as the cæcum and the transverse and pelvic colons, whereas in post-bacillary cases the whole abdomen is very tender and sensitive to pressure. These somewhat indefinite signs, however, are by no means always reliable.

Routine Uses of the Sigmoidoscope.

Many excellent arguments can be advanced for the routine employment of the sigmoidoscope in the diagnosis of these conditions, and we wish to lay stress upon some of the more important.

In chronic bacillary dysentery of several years' standing little or no assistance may be obtained by the employment of laboratory methods; for this failure the secondary pathological changes which have taken place in the mucosa of the large gut are responsible. These changes are due to the deposition of granulomatous and fibrous tissue resulting from the destruction of the mucous membrane; in bacillary dysentery this is usually more extensive in the lower portion of the rectum than elsewhere and consequently is easily visible through the sigmoidoscope.

It is hardly necessary to state that a simple microscopic examination of the fæces is not of much value in such cases, nor can one expect any assistance from attempts to culture the dysentery bacilli, either from the excreta or from scrapings of the mucosa, as these organisms have long since disappeared; for the same reason, serological reactions are no longer diagnostic. In chronic amœbiasis there are drawbacks also in establishing a definite diagnosis by any of the well-recognised methods of laboratory examination. It is now well known that in such chronic cases histolytica cysts may be passed in the fæces in an extremely irregular manner; it may be that they are present in considerable numbers on one or two occasions, so as to be easily visible under the microscope, but that subsequent examinations, for days or even weeks on end, may be negative as regards this organism. We may instance one particular case in which 11 fæcal specimens were examined daily with negative results during the fortnight the patient was in hospital for observation, but on the twelfth occasion numerous characteristic cysts were seen; this occurred while he was being actively purged and was passing stools containing much blood and mucus. Cases of a similar nature have been cited by others who have had a large experience of this disease; the value of repeated microscopical examinations in detecting *Entamœba histolytica* carriers has been ably emphasised by Dobell in his numerous publications on this subject. In 1917[4] he recorded a case which was diagnosed on the thirty-fifth consecutive examination, and doubtless there are more extreme instances than this. In his latest publication,[5] in summarising his experiences, he has stated that a series of such cases examined once apiece may be expected to disclose about one-third of the infections actually present; in a series examined thrice per case between one-half and two-thirds of the actual number of infections will have been detected. In order to be on the safe side, as a routine measure, six consecutive microscopical examinations would be necessary in every case. Even in more acute stages of the disease, when quantities of blood and mucus are being passed in which the active vegetative entamœbæ can be easily found, it does not necessarily follow that the characteristic histolytica cysts will appear in the fæces after the subsidence of the more acute symptoms. We have recently seen three cases who passed typical motions on one occasion, but whose stools were examined on several occasions after admission to hospital with negative results. To clinicians it is becoming obvious that, as a method of excluding amœbiasis in diagnosis, many microscopical stool examinations are required for each patient, and incidentally much delay must ensue before a diagnosis can be made or a rational treatment instituted. Any aid to diagnosis which will obviate this delay should be encouraged as saving both time and money. Having ourselves been engaged for a considerable period on routine stool examinations we do not wish to make any statements which would tend to bring such a well-established method into disrepute, but it has its limitations, as every experienced microscopist will admit.

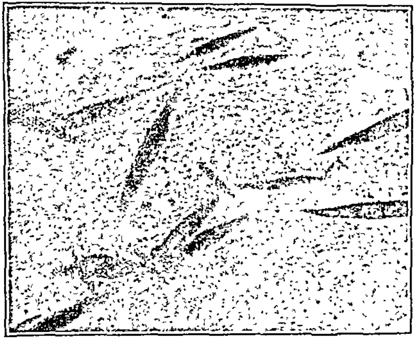

FIG. 1.—Charcot-Leyden crystals, × 1200. Preparation from scraping of amœbic ulcer through the sigmoidoscope, showing Charcot-Leyden crystals in numbers, stained by Heidenheim's hæmatoxylin (microphotograph by Dr. J. Gordon Thomson).

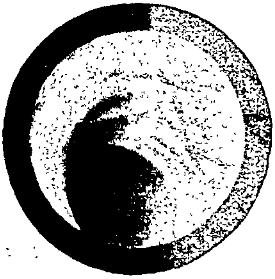

FIG. 5.—Chronic bacillary dysentery.—Grazed and granular appearance of mucosa due to formation of granulation tissues.

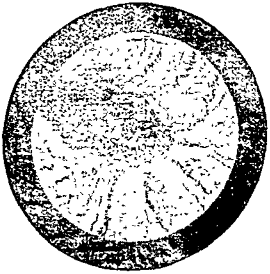

FIG. 6.—Chronic bacillary dysentery.—Deposition of granulation tissue and fibrosis.

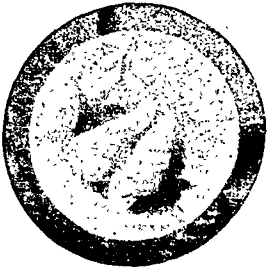

FIG. 7.—Chronic bacillary dysentery.—Showing large polypi (4 ins. from anus).

The advantages of the routine use of the sigmoidoscope may be stated as follows:—(1) A rapid and accurate diagnosis by direct inspection of the mucosa can often be made. (2) Pathological conditions other than dysentery, and often hitherto unsuspected, such as hæmorrhoids, syphilitic lesions, malignant disease or polypi are occasionally revealed. (3) The very large proportion of cases of doubtful ætiology, which by the employment of simple microscopical methods would remain undiagnosed, is reduced to a minimum.

Preparation of the Patient.

The method adopted in making a sigmoidoscopic examination is comparatively simple, but it is necessary to emphasise one or two points. The preparation of the patient requires consideration. He should be purged so that the large bowel is emptied of fæces, but at the same time it must not be rendered too irritable. We have found that the most satisfactory method consists in administering half an ounce of castor oil on the previous evening, followed in the morning by a soap-and-water enema so as completely to clear out the rectum. In order to decrease peristalsis and render the bowel less sensitive to manipulation we find it advisable to administer 15 minims of tinct. opii immediately after the enema. In cases where there is incessant diarrhœa a satisfactory method of clearing out the bowel has yet to be discovered, but, fortunately, in these cases a fleeting glimpse of a small portion of the bowel usually suffices to establish a diagnosis.

As regards the posture assumed to the patient during examination, we prefer the lithotomy position. This method allows any fluid contents of the bowel to collect in the dorsal curvature of the rectum, which acts as a sort of a trap, while the bowel, both above and below this pool, may be minutely scrutinised. It is quite unnecessary, indeed, to our minds it is disadvantageous, to administer an anæsthetic. One should be guided by the patient's sensations of pain or discomfort while the instrument is being passed; the former should not be present in examining a normal bowel. Naturally, when one intends to examine an ulcerated bowel, great care should be exercised in introducing the instrument, and when once the sphincter muscles have been passed its further passage should be guided by sight alone. The degree of pain experienced varies greatly. Generally it is much greater in the bacillary types than in the amœbic disease; it is much greater in highly-strung and nervous individuals than in less sensitive subjects. The ulceration of the bowel would seem to have little bearing upon this point, for some cases with extensive ulceration complain of little or no discomfort whilst being examined. It is wise not to disregard any sudden pain of which the patient complains, for this is generally due to too great pressure being exercised upon one particular portion of the bowel wall. The distance to which the instrument can be passed also varies considerably; in some a length of only a few inches, in others again 12 inches or so, may be reached with ease, and the point of the sigmoidoscope can be distinctly palpated in the left hypochondrium.

Sigmoidoscopic Appearances of Amœbic Lesions.

In those cases in whom the amœbic lesions extend into the rectum the appearances vary pretty considerably, but they are sufficiently characteristic to be diagnostic. As a rule discrete ulcers can be made out; they vary in shape and in size. Some are barely visible, while others are 6–8 mm. in diameter. No lesions occupying several inches in extent, such as often may be seen in the large gut at autopsy, have as yet been met with. The ulcers are usually oval or diamond-shaped; their margins are hæmorrhagic, and their bases covered with grey-coloured or greenish sloughs. In depth they also exhibit considerable differences; they may be quite superficial, or they may involve the submucosa (Fig. 1). The mucous membrane intervening between the individual lesions is healthy in appearance and of an orange-rose colour. Generally it is more redundant and reticulated than is the normal (Fig. 2).

Flame-shaped hæmorrhages are usually numerous; the smaller ones can be described as having a dark hæmorrhagic centre surrounded by an areola of a brighter hue. The larger ones may form patches of an irregular shape and may involve considerable areas of mucous membrane; others again of intermediate size lie concealed between the folds of puckered mucous membrane (Fig. 3). On the whole, the lesions resemble those seen in the large intestine at autopsy, but it has struck us that the small petechial hæmorrhages and the vivid coloration of the blood clots are much more apparent than when seen in the cadaver, which is only what one would expect from a study of living tissues.

As a further confirmation of the amœbic origin of e lesions the ulcers may be scraped and the exudate thereby obtained examined microscopically. A convenient instrument for this purpose is a wooden match affixed to a holder and introduced through the tube of the sigmoidoscope. By this means we have been able to demonstrate active entamœbæ often in considerable numbers, as well as Charcot-Leyden crystals, which are by some considered to be strongly suggestive of amœbiasis (J. Gordon Thomson[6] and H. W. Acton[7]), even in several cases in which numerous fæcal examinations failed to reveal either active entamœbæ or their cysts (Fig. 4). In a few cases of undoubted ætiology—that is to say, of microscopically diagnosed cases—the rectum and colon as seen by the sigmoidoscope were normal in appearance, and in these one has to presume that the amœbic lesions are situated in the upper portion of the large bowel beyond the range of vision through the sigmoidoscope.

Sigmoidoscopic Appearances of Post-Bacillary Lesions.

The changes seen in the lower bowel in this very serious condition consist for the most part of granulation tissue, and may be regarded as an attempt on the part of the bowel to replace, as far as is possible, the tissues originally destroyed by the toxins of the dysentery bacillus. Acute inflammatory changes, when present, are possibly due to a secondary invasion of the mucosa by other intestinal organisms. Up to the present we have not seen cases in which actual ulceration of the bacillary type was present in the rectum.

The changes observed by us may be classified according to their severity in the following manner:—

(*a*) In comparatively slight cases there is an injected and plush-like appearance of the mucosa, while the passage of the instrument is attended by considerable pain.

(*b*) In more advanced cases the mucosa is hyperæmic and has a granular or glazed appearance. The whole rectal canal may be in this condition, or definite annular zones, three or more inches in extent, may be affected (Fig. 5).

(*c*) Masses of granulation tissue, which is very friable and vascular, may be seen superimposed upon a much scarred and fibrotic membrane (Fig. 6).

(*d*) The most advanced stage represents merely an exaggerated phase of the process just described, and takes the form of vascular polypi attaining even as much as ¾ inch in length; the pathology of this curious polypoid condition was described by one of us[8] in a recent paper (Fig. 7). This polypoid condition may extend through the large intestine, for similar changes have been seen in the cæcum in two cases in whom the bowel was opened at operation. It is scarcely necessary to add that the clinical condition of these cases is one of great severity.

The table of statistics which follows will serve to illustrate the various points to which we have alluded in this paper.

DIAGNOSES IN 100 CONSECUTIVE CASES OF SUSPECTED DYSENTERY.

Diagnosis by Sigmoidoscope.

Positive amœbic ..	29	42
Suggestive of " ..	13	
Positive bacillary ..	15	28
Suggestive of " ..	13	
Other causes of symptoms:—		
Rectal polypus	1	
Hæmorrhoids	4	
Syphilitic stricture ..	1	
Ætiology undiagnosed	11	
Normal appearance	14	
	101•	

• This extra number is explained by the diagnosis of amœbic and bacillary infection in the same patient.

Diagnosis by Microscope.

Positive amœbic ..	30	31
Suggestive of amœbic (Charcot-Leyden crystals)	1	
Positive bacillary ..	0	5
Suggestive of " ..	5	
Remaining of no positive value (exams.)	211	
Total microscopical exams. done on these 100 cases ..	247	

These preliminary examinations were all performed before a diagnosis was established.

Details of Sigmoidoscope Results.

Forty-four positive diagnoses were made, and of these:—

20 were confirmed by the microscope.

15 others were confirmed by the clinical history of the patient.

In 8 the clinical history was doubtful and confirmation of the diagnosis is lacking.

In 1 the history disagreed with the diagnosis, which was subsequently proved to be correct on clinical grounds.

Twenty-six *suggested diagnoses* were given, and of these :—

6 were confirmed by microscope.
10 others were confirmed by the clinical history.
In 5 the clinical history was doubtful, and confirmation of *the diagnosis is lacking.*
In 5 our diagnosis was probably wrong.

Thus there were 52 confirmed diagnoses of amœbic or bacillary dysentery, and there were 6 cases in which the symptoms were caused by other local *conditions, such as* hæmorrhoids, &c.

Of the remaining 43 cases :—

11 were undiagnosed.
14 appeared normal, and of these :—
    In 1 the clinical history was doubtful.
    6 had no symptoms and were discharged.
    1 had *Entamœba histolytica* cysts and a liver abscess, but had never had dysentery.
    2 had *Entamœba histolytica* cysts in their stools.
    3 gave a history of amœbic dysentery.
    1 „ „ „ bacillary „
13 lack confirmation.
In 5 our diagnosis was probably wrong.

In other words, the sigmoidoscope was instrumental in giving a positive diagnosis—*that is, a confirmed diagnosis*—from a single examination in just 58 per cent. of our cases, while in the same 100 cases microscopic diagnosis, after repeated tests, gave about 30 per cent.

In conclusion, we wish to express our indebtedness to Dr. G. C. Low for generously permitting us to utilise figures obtained from cases under his care. Many of the routine microscopical examinations of fæces so frequently quoted in this paper were undertaken by Dr. J. Gordon Thomson, whom we also wish to thank *for his assistance,* as well as for his kind permission to reproduce his excellent microphotograph of Charcot-Leyden crystals (Fig. 4).

A METHOD OF OPERATION FOR THE TREATMENT OF ECTOPIA VESICÆ.

BY CHARLES ROBERTS, M.B., B.S. LOND., F.R.C.S. ENG.,

HON. SURGEON, MANCHESTER ROYAL INFIRMARY; *CONSULTING* HON. SURGEON, MANCHESTER CHILDREN'S HOSPITAL, PENDLEBURY.

THE modern treatment for ectopia vesicæ is to divert the ureters into the bowel. The trigone of the bladder may be transplanted into the sigmoid colon by the intraperitoneal route (Madyl, Stiles, Coffey), or the ureters may be transplanted into the rectum by the extraperitoneal route (Peters, Moynihan). I wish to describe a method of operation which I have employed in four cases of ectopia vesicæ with very satisfactory results.

Method of Operation, Advantages, and Age at which it should be Performed.

The operation consists briefly in transplanting the ureters directly into the rectum through its anterior wall above the level of the peritoneal reflection of Douglas's pouch, the general peritoneal cavity being shut off by suture before opening the bowel.

The operation is very simple to perform and can be completed in less than 30 minutes, thus involving little or no shock. It avoids the risk of infective peritonitis, owing to occasional leakage of the intraperitoneal operation, and the danger of subsequent retraction of the ureters into the bladder wound of the extraperitoneal method.

The operation should be postponed until the child attains the age of 2 years when the anatomical structures are large enough to facilitate the necessary dissection, manipulation, and suturing, and when the after-treatment can be carried out with greater satisfaction.

Preliminary Treatment.

Hexamine and acid sodium phosphate in suitable doses are administered to minimise the risk of ascending pyelitis. Occasionally after operation the child suffers from attacks of pyrexia accompanied by vomiting, irritability, and drowsiness, probably due to infective pyelitis. These attacks are liable to recur but tend to diminish gradually and can be controlled by giving urinary antiseptics. The skin is prepared in the usual way and the rectum is cleansed by frequent irrigation. The exact position of the ureters should be determined in order to avoid delay at the time of operation, as the orifices may lie rather concealed in folds of mucous membrane.

Description of the Operation.

The pelvis is raised on a small sandbag. I prefer to stand on the left side of the patient. After passing a small probe, a No. 2 Black French catheter (the end of which has been removed to leave a terminal opening) is inserted into each ureter for a distance of from 2 to 3 *inches,* and is sutured in position by *a fine* catgut suture inserted *with a fine* straight needle which *transfixes* the catheter and the bladder *mucous* membrane at a distance of ½ inch from the summit of the *ureteral papilla.*

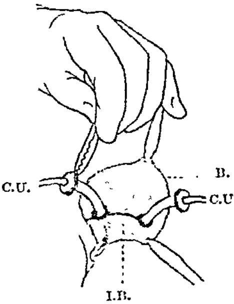

FIG. 1.—C.U., Catheter in ureter. B., bladder. I.B., Incision through bladder between ureteral pouches.

The mucous membrane is then incised circularly at a distance of 1 inch from the orifice of the ureter and the incision is carefully carried through the bladder wall until the wall of the ureter is reached. Great care must be taken not to injure the ureter and its vessels. The ureter is freed by dry gauze dissection, and by snipping a few fibrous bands with scissors or scalpel, until about 2 inches of the ureter can be drawn into the wound (Fig. 1). The assistant then inserts a finger of the right hand into the rectum and presses its anterior wall into contact with the posterior wall of the bladder at a level well above the uterus, which can be readily felt in the female, and at a corresponding distance in the male. The bladder wall lying between the ureteral *pouches* is *then* incised transversely (Fig. 1) on to the assistant's finger until the peritoneal cavity is *opened,* when the anterior rectal wall at once protrudes through the incision thus made (*Fig. 2*).

Fine catgut sutures are passed through the cut edges of the bladder *wall and* the *sero-muscular* coat of the rectum so that an area of the anterior surface of the rectum *measuring* about 2 in. by 1 in. is completely shut off from the general peritoneal cavity (*Fig. 3*). Through this area a transverse incision about 1½ inches long is made into the bowel whilst the assistant partially withdraws his finger (Fig. 3). The catheters are then passed through the opening, taken by the assistant, and carefully drawn from the anus until the ureters with their surrounding *mucous* membrane lie just within the rectum. The opening into the rectum is then closed with catgut sutures in such a manner that the ureters are fixed firmly at the angles of the wound (Fig. 4). The transverse incision in the bladder is sutured over this. No attempt is made to remove any of the bladder wall. This is better dealt with at a second operation.

After-Treatment and Results.

The ureteral catheters commence to drain within a few hours and become loosened within 5 or 7 days, when they are withdrawn. If either catheter ceases to drain before this it must be removed and can easily be loosened by twisting movements, traction being avoided. Hexamine and acid sodium phosphates are given for the reasons previously mentioned.

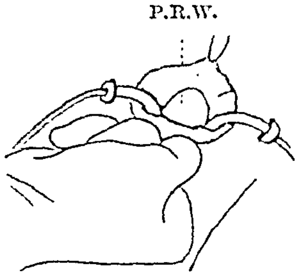

Fig. 2.—P.R.W., Pouch of anterior rectal wall pushed through bladder incision by finger in rectum.

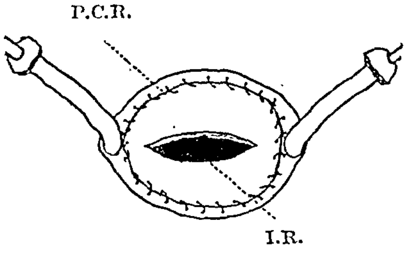

Fig. 3.—P.C.R., Peritoneum covering of rectum stitched to peritoneum covering of bladder; I.R., Incision into rectum.

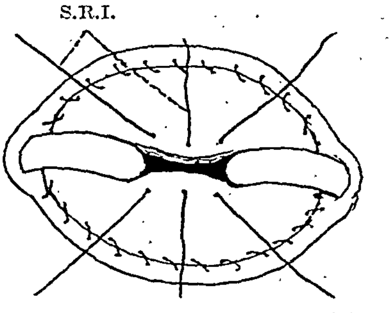

Fig. 4.—Ends of ureters inserted into rectum. S.R.I., Sutures closing rectal incision.

About six months later the mucous membrane of the bladder is excised and the raw surfaces brought together by under-running strong silkworm-gut sutures. The transplanted ureters readily accommodate themselves to their new anatomical relations, and development is not interfered with.

At the provincial meeting of the Section of Diseases of Children of the Royal Society of Medicine held in Manchester in July, 1920, I showed a patient on whom I had performed this operation in October 1908. The uterus appears normally developed and she menstruates regularly. The rectum carries out its double function independently. Fæcal evacuation usually occurs once daily and urine is voided separately, three or four times by day and not at all during the night. The diagrams have been made from photographs taken during an operation, and I am much indebted to Dr. W. E. Fothergill, who has kindly drawn them for me.

OBSERVATIONS ON THE
UREA CONCENTRATION TESTS IN THE PSYCHOSES.

By J. WALKER, M.B., Ch.B.Edin., D.P.H.,
SENIOR ASSISTANT MEDICAL OFFICER, CARDIFF CITY MENTAL HOSPITAL, WHITCHURCH, GLAM.

The primary objects of this investigation were to discover if there is any undue prevalence of renal inefficiency in the psychoses, as determined by the urea concentration tests in the blood and urine, and, if so, with what forms of mental disorder this condition is associated. During the progress of the investigation it was observed that several cases showed a low urea concentration in the urine with either a normal or subnormal blood concentration. It was therefore thought desirable to estimate the daily excretion of urine with the total excretion of urea and ammonia and the percentage urea concentration in the same. The urea nitrogen and ammonia nitrogen ratio was also determined.

Concentration Tests in the Blood and Urine.

The tests employed were those described by H. MacLean and A. E. Russell,[1] and their instructions as to diet, &c., prior to the tests were strictly adhered to. The urine test commenced at 10 A.M.—i.e., about 2½ hours after a breakfast consisting of bread, butter, and tea. The patient was then put to bed and no further fluid permitted until the completion of the test. Printed instructions were issued on the occasion of every test. The blood was withdrawn between 11.30 A.M. and 12 mid-day—i.e., at the corresponding time, but either on the day prior to or following the urine test. Sufficient blood was always collected to enable a duplicate examination to be made, the average of the two estimations being taken as a measure of the urea concentration. The tests were repeated in a few cases, but as the results were more or less the same it was not considered necessary to do this in all cases.

Prior to and during the collection of a 24-hour specimen each patient received a fixed diet consisting of two pints milk, two eggs, milk pudding, with bread-and-butter. The total excretion of ammonia was estimated by the formalin method. Albumin in all cases was tested for by the salicyl-sulphonic acid and heat tests. The systolic blood pressure was determined during the clinical examination of each case.

Before the results obtained in this investigation are considered, it is necessary to have a clear understanding as to what are considered the normal limits of urea-concentration in the blood and urine. In spite of the fact that W. MacAdam and Bentley Squire[2] give the maximum blood concentration of 25 mg. and 12·5 mg. per cent. respectively, I consider that MacLean's maximum of 40 mg. per cent. is none too high. In Tables I. and II. are cases with a much higher blood concentration with a urine concentration not only between the normal limits of 2 and 4 per cent. as set out by MacLean, but even greater than 4 per cent. Clinical as well as other evidence was contrary to a diagnosis of renal disease in each of those cases. The lowest and highest percentage concentration of urea in the blood found by me in cases showing no evidence of renal disease are 9 mg. and 83 mg. per cent. respectively. But basing my result on the normal standard percentages by MacLean—viz., 15 to 40 mg. per cent. in the blood and 2 to 4 per cent. in the urine, I find there is a large percentage of cases giving abnormal results in which the diagnosis of renal disease, apart from the tests referred to, is not justified.

Eighty-three cases have been investigated. Table III. gives these cases grouped according to their mental disorder with the findings in each. It is seen that 36 per cent. have a normal urea concentration in the blood and urine, according to the limits referred to above. This is a very low percentage. If the cases showing a normal blood concentration with a urine urea concentration below 2 per cent. in which the low urine concentration appears to be due to diuresis, that is, when the total urine excreted in the first and second hours together exceed 350 c.cm.—this diuresis is especially frequent in dementia præcox, and will be discussed later—are considered for the present to be consistent with a healthy condition of the kidneys, the percentage of normal cases is raised to 52. Again, if cases with a normal urine concentration and a blood concentration below 15 mg. per cent. are included for the same reason, the percentage of normal cases is raised to 57. Of the 43 per cent. of the cases remaining only four could reasonably be considered to be suffering from kidney disease (see Table IV.), and in this connexion it is worthy of note that only two of them have a blood urea concentration over 40 mg. per cent., while they all show a low urea concentration in the urine.

---

[1] The Lancet, 1920, i., 1335.

[2] Brit. Med. Jour., 1921, i., 290.

Tables V. and VI. give examples of the remaining unclassified 38 per cent. of the cases. Table V. deals with the cases showing a blood concentration over 40 mg. per cent. in all of whom the urine urea concentration is below 2 per cent. Table VI. deals with the cases having a blood concentration below 15 mg. per cent. and a urine concentration below 2 per cent. The question now arises: Should this 38 per cent. be regarded as explicable by kidney disease, no evidence, clinical or otherwise, being available other than that derived from the concentration tests to warrant such a conclusion? Two explanatory hypotheses are possible in this investigation. These tests were carried out in cases where a nervous or mental element was present as an extra or complicating factor, and perhaps there is in the psychoses, and more especially in dementia præcox, melancholia, and confusional states, a greater incidence of renal disease in a degree not revealed by the ordinary clinical methods than has hitherto been realised. The second and perhaps more plausible hypothesis is that in the psychoses there may be present some factor or factors other than kidney disease to account for the anomalous results obtained. The latter theory is strengthened by three other observations made in the cases of dementia præcox examined—viz., the coexistence of diuresis, polyuria, and acidosis.

Dementia Præcox.

Table VII. deals with the cases of dementia præcox in which it has been possible to compare the results of the concentration tests with those found in the urine excreted in the 24 hours. Although it is wrong to make deductions from a small number of cases, it is worthy of notice that all cases of dementia præcox so far examined show, without exception, a moderate to a marked degree of acidosis, the ammonia nitrogen reaching as high as one-tenth of the urea nitrogen in 4 of the 8 cases. Acidosis was not found in mania, melancholia, and insanity with epilepsy, but a mild degree was found in all of the 8 cases of confusional insanity so examined, and a very severe degree in the only case of general paralysis examined, the ammonia nitrogen being as much as a fourth of the urea nitrogen.

From Table III. it will be seen that diuresis has occurred in almost half of the cases of dementia præcox. From Table VII. it is observed that a low urine urea concentration has been found not only in the concentration tests, but also in the 24-hour specimens. The low urine urea concentrations found in the cases of dementia præcox in Table VII. will confirm this observation. From Table VII. it is seen that there is a high urinary excretion in the 24 hours. In the other psychoses in which the 24-hour excretion of urine has been measured, the amount is found to be low and the urea concentration high. It is difficult to speculate as to the significance of these observations, other than that it may be more than probable that in dementia præcox there exists some general disturbance and not renal disease to account for these anomalous results, such as either a disordered protein metabolism or some form of endocrine disturbance implicating more particularly the pituitary gland.

Summary.

(1) The urea concentration in the blood in the cases examined is subject to wide variations, and therefore

TABLE I.—*Cases without Kidney Disease.*

Blood urea percentage above 40 mg., and urine urea concentration above 4 per cent.

Name.	Age and sex.	Urine conc' test. Amounts (c.cm.). 1st hour.	Urine conc' test. Amounts (c.cm.). 2nd hour.	Percentage conc. urea in 2nd hour.	Specific gravity.	Reaction.	Albumin.	Blood urea %. D. B. L.	35, F.	—	65	3·5	1032	A	0	57	—	—	—	—	—	Melancholia.	Moderate health; slight glycosuria. S.B.P. 102 mm.

* Optic and peripheral neuritis. Noteworthy that acidosis not present.

Remarks.—Three cases showing a *high blood urea* concentration, with a normal urine urea concentration. It is noteworthy that glycosuria is present in two cases. The explanation other than kidney disease may be that an excessive protein *metabolism* coexists with a disordered carbohydrate metabolism. The type of mental disorder predominating is confusion with a moderate degree of excitement.

* The U and N ratio signifies that a moderate degree of acidosis was present.

Remarks.—The above six cases should be regarded as cases of renal inefficiency according to the urea concentration tests. It is noteworthy that in three of the cases where the urea N and ammonia N ratio has been determined a condition of acidosis is found to coexist; that they are all adolescents with ages ranging from 17 to 31 years; that the total urea output is within normal limits in each case examined: that dementia præcox is well established in two cases and in the early stages in two others, in all of whom the systolic blood pressure is above normal.

TABLE VI.—*Cases without Kidney Disease.*

Blood urea below 15 per cent. and urine urea concentration below 2 per cent.

Name.	Age and sex.	Urine conc. test. Amounts. 1st hour.	2nd hour.	Urea percentage in 2nd hour.	Urine— Sp. gr.	Reaction.	Albumin	Blood urea %.	Mental state.	Physical state, &c.
M. D.	45, F.	90	190	1·06	1010	Alk.	0	15	Melancholia.	Good health. S.B.P. 130.
A. S.	30, F.	320	115	1·42	1014	A	0	11	Dementia præcox.	" " 125.

A. M.	31, M.	290	160	1·5	1015	A	0	12	Confusional insanity.	Fair health. Alcoholism. S.B.P. 118.

Remarks.—The cases of dementia præcox in the above table show a low blood concentration and a low urine concentration. Diuresis is present in all except one case. The low blood and urine concentrations may be due to a lower rate of metabolism, especially that of the protein moiety. This is noteworthy in connexion with dementia præcox.

TABLE VII.—*Dementia Præcox.*

The presence of kidney disease has been excluded by clinical and other available methods.

* An early and doubtful case of dementia præcox.

Remarks.—All the cases are adolescents. The total daily urea output is within normal limits, but there is an increase in the total mmonia excreted. The urea nitrogen and ammonia nitrogen ratio is normal and points to the presence of a state of acidosis. There is a w urine urea concentration in the urine excreted in the 24 hours as well as in that of the concentration test associated with polyuria d diuresis. The urea concentration in the blood is variable.

is an unreliable guide as to the state of health of the kidneys.

(2) The urea concentration in the urine gives more reliable information. A low concentration should be regarded only as a confirmation of other evidence.

(3) Anomalous results, both as regards urea concentration in blood and urine, apart from kidney disease, are as demonstrable by available methods common in the psychoses.

(4) In dementia præcox a low concentration of urea in the urine is found to coexist with polyuria and a state of acidosis.

A CASE OF OSTEITIS FIBROSA,

TREATED BY RESECTION OF FOUR INCHES OF HUMERUS AND INSERTION OF BOILED BEEF-BONE GRAFT.[1]

BY C. W. GORDON BRYAN, *M.C.*, F.R.C.S. ENG.,

SURGEON TO OUT-PATIENTS (ADDITIONAL) AND ORTHOPÆDIC SURGEON, ST. MARY'S HOSPITAL; SURGEON TO OUT-PATIENTS, PADDINGTON GREEN CHILDREN'S AND HAMPSTEAD GENERAL HOSPITALS.

IT is an accepted fact that for bridging wide gaps in adult bones it is necessary to make use of autogenous bone grafts, but the work of Gallie and Robertson[2] showed that for short gaps, even in healthy bones, boiled grafts might be used with the expectation of the gap being ultimately bridged by living bone. König's work[3] on the use of massive ivory grafts showed that these became firmly united to the living bone, the surface of the graft being soon pitted by ingrowth of granulation tissue. Barth[4] showed many years ago that dead bone and ivory could heal into the tissues and become incorporated with or substituted by the living bone.

In children the conditions differ from those of adult bone, especially when the gap is situated near the growing end of the diaphysis, and when proliferation of subperiosteal bone cells is already present as a result of inflammation or injury; in such cases it is reasonable to expect that a dead graft will be as efficient as a living autogenous one, for it becomes rapidly united to the living bone, and surrounded by new bone from the periosteum.

In the case described below use was made of a boiled beef-bone graft to fill a gap of four inches left by resection of the upper part of the humerus for osteitis fibrosa.

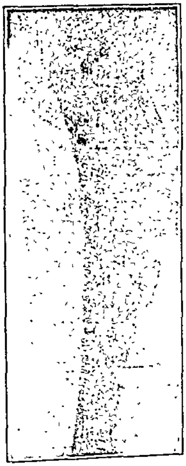

FIG. 1.—Showing localised rarefaction and expansion, with fracture. (Nov. 5th, 1920.)

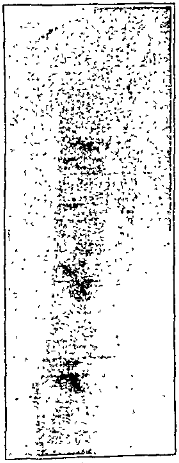

FIG. 2.—One month after operation. Beef-bone graft united to humerus; much new bone from periosteum on the inner aspect, and small areas of new bone externally. (Jan. 6th, 1921.)

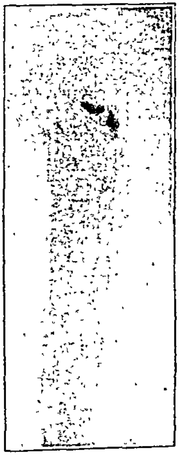

FIG. 3.—Three and a half months after operation. Showing dense new bone surrounding the graft. (March 24th, 1921

The notes of the case are as follows:—

A. C., a girl of 10 years and 9 months, admitted to Paddington Green Children's Hospital on Nov. 25th, 1920.

History.—Four days previously she fell prone, and the right arm became useless. In February, 1919, she had been admitted to another hospital for pain in the arm following a fall; X rays showed a localised area of rarefaction in the upper part of the humerus. An operation was performed, the bone being opened, and an area of soft tissue in its interior was removed by the curette. Microscopic examination showed this to be fibrous tissue.

Family history.—One child died from bronchopneumonia, another from convulsions. Two others are alive and healthy. No miscarriages. No other family illness.

Condition on admission.—Signs of fracture (pain, crepitus, slight deformity) of the upper end of the right humerus, with little displacement. X rays (Fig. 1) showed a rarefied and expanded area in upper third of humerus, with pathological fracture.

Nov. 29th, 1920: Plaster case made in two pieces, including arm, forearm, and thorax, the arm being in a position of abduction flexion and external rotation.

Operation (Dec. 7th).—Six-inch curved incision at the anterior margin of the deltoid. The bone was extensively destroyed and replaced by fibrous tissue, there being a thin shell of compact bone (fractured) postero-internally; the periosteum was absent anteriorly for one-third of the circumference of the bone, the muscles forming a pseudocapsule for the fibrous mass. The bone was divided above and below the diseased part, after the remaining periosteum had been separated, four inches of the humerus being removed. The beef-bone graft was then inserted, its lower peg extending into the medulla of the lower fragment of humerus, its upper end being wedged into the cancellous bone above. This graft had been cut from the tibia of an ox and was macerated and boiled for about 48 hours; it consisted of compact bone, and was 5 in. long, 7/8 in. wide, 1/3 in. thick; it was shaped by an Albee's saw and by filing, and drilled by multiple holes transversely, and also longitudinally at each extremity. The muscles and periosteum were sutured round the graft with catgut, and the wound closed without drainage; the plaster cast was then reapplied. On the 11th stitches removed, primary healing. From the end of the third week the plaster was removed each day to allow of careful active movements; the bone appeared to be firmly united within three weeks of the operation. The patient left hospital in the plaster on Jan. 5th, 1921.

Jan. 6th: X rays showed considerable formation of new bone on the inner aspect and small areas of new bone on the outer aspect of the graft, having apparently extended through the drill-holes (Fig. 2). On the 10th all passive movements normal; active abduction slightly diminished, other active movements normal. On the 23rd plaster case finally discarded, since which date no appliance has been used, the patient being allowed to employ the arm normally.

---

[1] Shown at meeting of Clinical Section of the Royal Society of Medicine, April 8th, 1921.

[2] Brit. Journal of Surg., October, 1919, vol. vii., No. 26, p. 211.

[3] Beitr. z. klin. Chir., 1913, xlii., p. 353.

[4] Arch. f. klin. Chir., 1893, xlvi., p. 409.

Feb. 4th: From this date the condition has been as it is now, with firm union, no wasting, full abduction, full range of rotation, with slight excess of external rotation, and a similar slight degree of diminution of internal rotation. The limb was lightly massaged twice a week for five weeks, commencing on Jan. 23rd.

X ray photographs taken on Jan. 27th, Feb. 24th, and March 24th (Fig. 3) show gradual increase of new bone, of increasing density, surrounding the graft, and apparently filling the drill-holes. Histological examination of the specimen showed the typical appearances of osteitis fibrosa.

Report on Pathological Tissue Removed at Operation.

Dr. H. Perkins, pathologist to the hospital, has kindly provided a report on the specimen, which he also submitted to Dr. E. H. Kettle, of St. Mary's Hospital, for confirmation.

"The continuity of the bone shaft is lost in an irregular mass of new tissue, which is pink in colour, of great firmness, and not very vascular; this tissue occludes the medullary canal, and no cysts are present. Histologically, the mass consists chiefly of firm fibrous tissue in which there are very few blood-vessels. In some parts a more cellular growth is found, consisting chiefly of spindle-shaped cells; the transition from spindle-shaped cells to firm fibrous tissue can be observed in the section. With the spindle cells are many multinucleate giant cells, but their character does not suggest malignancy."

Summary.

The method seems to the author to present the following advantages:—

1. It was not necessary to interfere with another bone of the patient for provision of the graft; fracture of the tibia has in several cases followed long after the removal of bone for a graft.
2. The beef-bone graft was much stronger than any autogenous graft that could have been used, and the function of the arm was fully restored in seven weeks: at this time all retentive apparatus was discarded, and from that time the limb has been used normally.
3. The avoidance of prolonged immobilisation allowed the muscles to recover their size and function very rapidly, and prolonged treatment by massage, &c., was avoided also.

In fact, the patient has merely been kept under observation, and has not had treatment (except four weeks' massage) since seven weeks from the date of the operation.

PROFESSIONAL AND BUSINESS WOMEN'S HOSPITAL LEAGUE.—The annual report of this League for the year ending Dec. 31st, 1920, states that the League has steadily increased in numbers and that the general position is very satisfactory. The League, to which we have already referred (THE LANCET, 1920, ii., 1266), was founded in 1913 to make provision in severe sickness for women who earn their living in professional and business callings. On July 1st the committee concluded a contract with the St. Andrew's Hospital, Dollis Hill, on similar lines to that in force with the South London Hospital, by which accommodation is provided in a private ward for ordinary members of the League. Special grants are paid for treatment on behalf of provincial members who are unable to come to either of these hospitals for treatment, and occasionally for other cases who for some sound reason appear unable to avail themselves of the benefits arranged in the hospitals. Since the ordinary members subscription of 5s. per annum cannot entirely pay for the benefits offered, the League is still to a great extent dependent on the subscriptions of vice-presidents and hon. members, who receive no benefits. It is hoped that those who employ professional or business women will subscribe. County committees are being formed to enlist sympathisers and members, to collect money, and generally to aid the League. Owing to the enterprise of Mrs. W. S. Pedley, of Eastbourne, a branch in Sussex has already been started. The president of the ague is Lady St. Cyres. Further information can be ained from the Secretary, Miss Mildred Ransom, at the tered Office of the League, 195-197, Edgware-road, don, W. 2, to whom donations may also be sent.

A NOTE ON EXTERNAL DISLOCATION OF THE PATELLA.

BY RUSSELL F. MADDREN, M.D.

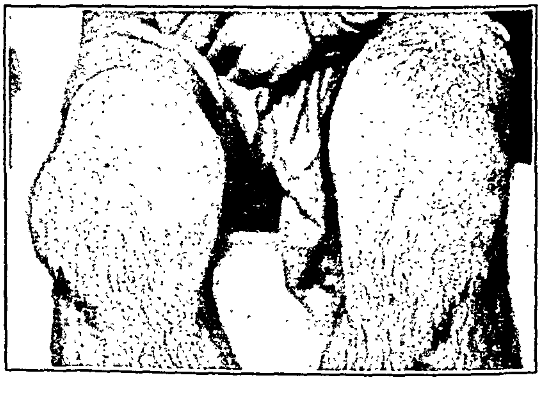
(From the Department of Experimental Surgery, New York University, U.S.A.)

THE bibliography of patella dislocation has become so extensive that the report of a single additional case would not appear justifiable unless it presented unusual features. As long ago as 1836 Malgaigne was able to collect 25 examples of patella luxations, and at present two or three cases apply every year to the average metropolitan hospital. Most of these patients, however, are adolescent females, whose patellæ occasionally slip out over the external epicondylar ridge because they suffer from genu valgum or some developmental deformity of their lower extremities. The multiplicity of operations that have been devised to correct this lesion suggests that surgical treatment is not invariably satisfactory.

Possession of a patella is "more a luxury than a necessity," as Hood demonstrated; its absence only affects an individual unfavourably if the extensor mechanism of his leg has become relaxed by disease or injury. One calls to mind that the kangaroo has no bony patellæ. In my patient the location of his right patella precluded its acting as a fulcrum, but, notwithstanding this, locomotion was perfect.

The Case Described.

In March, 1920, J. A., male, aged 34, was sent to me for physical examination preliminary to employment. Aside from the fact that his right patella was displaced externally, no abnormality was discovered. His general condition and muscular development were excellent. He demonstrated that he could run up and down the examining room doing an "about-face" when bidden without the slightest limping, hesitation, or embarrassment. He was passed as fit. During the ensuing three months, or until he left the company's service and was lost to sight, this man, whose work required him to wheel a barrow all day, was repeatedly examined by others as well as by the writer. No amount of manipulation would replace his dislocated patella in the trochlea—which was not as in Schaffer's case, the site of an exostosis. Both patellæ were apparently equal in size. The patient was quite certain that his right leg had never been injured and insisted that it had been in its present condition as long as he could remember. His mother had told him that the "lump" on the outer side of his knee had "always" been there. None of his relatives had similar deformities. His finger-nails were normal.



External dislocation of the patella.

This was not a case of the familial type described by Little and by Wirth. There was no other bony deformity of his lower extremities.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

WAR SECTION.

INFLUENZA IN THE NAVY.

A MEETING of this section of the Royal Society of Medicine was held on May 9th, Surgeon Rear-Admiral Sir ROBERT HILL, the President, in the chair.

Surgeon-Commander S. F. DUDLEY read a paper detailing his observations on the influenza pandemic of 1918 and 1919 as seen in the Navy. He attributed his occasional failures to isolate the *B. influenzæ* from influenza patients entirely to faulty technique, but considered that the reported absence of this organism from certain groups of cases may have been due to a secondary organism which had gained access as the result of a primary infection with *B. influenzæ*. He stated that during the past two years a carrier-rate of about 50 per cent. was constantly found for *B. influenzæ* among healthy sailors, and the percentage of positive results showed no relation to influenza prevalence. The three main factors relating to the nature and severity of epidemics were infectivity, virulence, and susceptibility. The greater the degree of infectivity in a parasite, the greater was its chance of infecting fresh hosts; while virulence was really a handicap to the parasite, as it limited the opportunities for multiplication and dispersal of the species beyond a single host, since corpses had few chances of disseminating diseases. On the other hand, the carrier, who was really the mildest of cases, frequently distributes his parasites. Also the less virulent strains of an organism generally stimulated less resistance on the part of the host, and therefore were more likely to succeed in adapting themselves to their environment. A parasite of sufficient infectivity might appear (possibly by the mutation of a less infective, but similar organism) and spread through a susceptible population as an epidemic. As the population gradually acquired a higher and higher degree of immunity, the more infectious strains of the parasite survived, and the more virulent strains become eliminated, ultimately resulting in a multitude of so-called carriers. The handicap of virulence, however, might not be felt as long as susceptible hosts were sufficiently numerous, and in the earliest days of an epidemic infectivity and virulence might increase together. Secondary organisms associated with the primary agent of influenza were probably the chief cause of its variable symptomatology and virulence, and were usually present from the outset of the disease, suggesting that influenza might always be a compound infection, and that mutualism and symbiosis have a share in the ætiology.

Statistics of the pandemic as it affected ships in the Royal Navy illustrated some points better than figures obtained ashore. In those ships that experienced two waves in 1918, the attack-rate in each wave was roughly 25 per cent.—that is, 50 per cent. were attacked in the year. The latter figure was the same as the attack-rate of those ships which were only attacked in the autumn, after they had completely escaped the earlier wave. The simplest explanation was that in the spring of 1918 only a quarter of a ship's company were susceptible to the prevalent strain of influenza germ. After a while it gained in infectivity, so that in the autumn, on its return, influenza was able to infect a further quarter of the men whose immunity had been good enough to withstand the spring type.
